Scanning Electron Microscopy of the Normal and Pathologically Altered Organ of Corti

by Goran Bredberg,[1] Harlow W. Ades[2] and Hans Engström[1]

INTRODUCTION

The authors have published a series of articles over a period of several years dealing with the morphology of the inner ear of animals and man. Many of those have been devoted to a systematic mapping of the sensory cells and nerve elements of normal and pathologically altered cochlear and vestibular epithelia. They were predicated initially on the idea of portraying properly the cell destruction caused by noise and ototoxic antibiotics. It was considered further that they would gain by the application of electron microscopic techniques. Transmission electron microscopy, while yielding illuminating insights on certain qualitative factors, did not give a quantitative estimate of the sensory cell population in normal or damaged cochleas, as it was known it would not. This left a need for a method of quantitating cells throughout the sensory organ, which in turn led to the development of the surface specimen method by which each sensory cell of the organ of Corti can be examined *in situ* and the entire organ mapped accordingly by light/phase contrast microscopy.

During the further development of the surface specimen method and its application to problems of noise exposure, the technique of scanning electron microscopy became available to us, and has proven to enjoy certain advantages over both light/phase contrast microscopy and transmission electron microscopy though it does not supplant either. What it does in part is to bridge the wide gap between light microscopy and transmission electron microscopy. It is an additional adjunct to the study of the inner ear, and only by the judicious combinations of methods and their convergence on the same problems can progress be firmly made. Thus, conventional transmission electron microscopy has been used widely and has contributed greatly to the knowledge of inner ear morphology. Likewise, light/phase contrast microscopy has clarified, both before and since, many interesting aspects of the morphology of both cochlear and vestibular portions of the inner ear. Scanning electron microscopy has

Fig. 1. In Fig. 1A the organ of *Corti* of cat is seen in conventional midmodiolar section. Both sensory cells and supporting elements are easily recognized. In Fig. 1B corresponding specimen from guinea pig has been photographed in the scanning electron microscope (SEM). The inner hair cell (*IHC*) and three rows of outer hair cells (1 → 3) are seen. Basilar membrane (*BM*). Tectorial membrane (*TM*). (A) 370, (B) 375

already had a considerable impact on this research illuminating structures which were previously seen dimly or not at all. It does so by showing true three dimensional pictures with a great depth of field and good resolution. It has added a new dimension to cochlear morphology which while mainly in the realm of surface features, is applicable to a more limited degree to subsurface structures as well. It has proved to have great advantage in visualizing features which have hitherto been seen in three-dimensional view only through re constructions.

In recent years a number of studies have accumulated relating to scanning electron microscopy on biological specimens. Biological applications have been reviewed by Hayes et al (1966) Hayes & Pease (1968) Barber & Boyde (1968) and Small & Marszalek (1969). The inner ear was first studied with the scanning microscope by Barber & Boyde (1968) in their study of ciliated epithelia. Lim & Lane (1969 *b c*) Lindeman (1970) and Kellerhals et al. (1970) studied the vestibular epithelia. The cochlea was studied by Lim & Lane (1969 *a c*) Bredberg et al (1970) Engström et al (1970) Marovitz et al. (1970) Thalmann et al. (1970) and Lundquist et al. (1971). The earlier studies on the inner ear were accomplished with air dried specimens (Barber & Boyde 1968 Lim & Lane 1969 *a b c*) but they showed many artefacts due to shrinkage and compression. Since then the techniques of preparation have improved greatly and there are a number of papers in which they have been discussed (Small & Marszalek 1969 Bredberg et al. 1970 Marovitz et al. 1970)

Most of the pictures presented in this paper represent some aspect of the normal morphology of the organ of Corti. They illustrate the three-dimensional structure in a new way that was made possible by the scanning electron microscope. There are a few figures, mainly transmission electron micrographs, which show the interrelationship and interdependence of transmission electron microscopy and scanning electron microscopy or illustrate in a different way what is seen in a scanning picture. There are some few figures which are taken from pathological cochleas, or fetal cochleas, and are included to provide illustrations of a few things that can be done with scanning electron microscopy and to indicate a few obvious areas of future research. This presentation in no way claims to give a complete picture of the morphology of the organ of Corti. For detailed information the reader is referred to Engström et al (1966) Spoendlin (1966, 1970) Iurato (1967) Bredberg (1968) Engström & Ades (1971)

METHODS

A specimen which is to be studied under the scanning electron microscope must fulfill certain minimal requirements.

1. Its size must be small enough to allow it to be mounted in the specimen chamber. The specimen normally up to 10 mm maximum diameter is glued to a metallic holder although there is now a stage and specimen holder that can accommodate one of five times that size (however it should be kept in mind

that a specimen of this size cannot be studied as a whole, but only as a series of parts)

2. It must tolerate the high vacuum of the microscope. When scanning electron microscopy was first developed, its use was confined to the study of hard materials which met the requirement of tolerance to high vacuum. Difficulties arose as investigators sampled biological specimens which consist mostly of water because this component had to be removed without significantly altering the shape of the remaining structure. Freeze drying techniques can generally accomplish this now. The most comprehensive paper on the preparation of animal tissues for scanning electron microscopy was written by Boyde & Wood (1969) in which they surveyed the problems encountered in the preparation of biological specimens, offered advice, and gave a number of technical details on how to manage the preparation.

3. It must be electrically conducting in order to remove electrons bombarding it. The electrons reaching the specimen must be conducted away or the specimen will be charged by the electron beam, which will disturb the secondary electrons or the electron beam itself. If the specimen is metallic, this problem is automatically solved but for non-metallic specimens, as we were using, a thin layer of conducting material must be applied. It must have good conducting qualities and should be a substance of high atomic number that will give a high emission of secondary electrons, thus giving a good signal. Gold or a combination of gold and palladium are commonly used however copper aluminum, and carbon may be used for special purposes.

The experimental animals (guinea pig, cat, monkey and chinchilla) were anesthetized with Nembutal before decapitation and removal of temporal bones. The perilymphatic cochlear spaces were perfused with a fixative. One of three fixatives was used. (1) A modification of Parducz (1966) consisting of 6 parts 2% phosphate buffered osmium tetroxide (Millonig, 1961) and 1 part saturated $HgCl_2$. (2) 1.5% veronal buffered osmium tetroxide solution, (3) 1.5% veronal buffered glutaraldehyde.

The human cochleas were fixed by injecting the fixative selected into the perilymphatic spaces 2–6 hours post-mortem and leaving it in the labyrinth until the temporal bones were removed at autopsy (method described in detail by Bredberg, 1968). The time of fixation with the Parducz fixative and with the buffered osmium tetroxide was 1–2 hours, and with glutaraldehyde 2–4 hours. After glutaraldehyde fixation, the specimens were kept in 1.5% veronal buffered OsO_4 for hours. Fixation of the human cochleas was subject to much more variation since it was not always possible to get access to the temporal bones at the desired time of fixation, hence the time could be up to 24–48 hours.

After fixation, the specimens were rinsed in glass-distilled water and dissected under a preparation microscope. In the guinea pig, the bony capsule around the cochlea was easily opened with watchmaker's forceps, whereas in the cat, the chinchilla and the monkey, in order to gain access to the organ

of Corti the bony capsule had to be thinned down with diamond dental burrs before it was opened. The method of dissection is essentially the same as de scribed by Engström et al. (1966) and Bredberg (1968).

The bony capsule was opened and the spiral ligament was removed with

Fig 7 The tunnel region surrounded by inner (*IP*) and outer (*OP*) pillars Through the tunnel, above the basilar membrane (*BM*) several radiating tunnel fibres (*RTF*) are seen. Three rows of outer hair cells (1 ... 3) are also seen Cat. 1 800

great care The osseous spiral lamina was dissected free with the organ of Corti in half coils or smaller segments, and placed in a jar of glass-distilled water At this stage the tectorial membrane covering the surface of the organ of Corti was removed and discarded unless it was to be studied *in situ* in a particular specimen The dissection was carried out further in some specimens to include the modiolus and modiolar aspect of the organ of Corti.

The specimens were placed in a drop of glass-distilled water on a thin aluminum plate. They were initially frozen by rapidly dipping the plate into isopentane which was kept just above its freezing point at −150° to −160 C by means of liquid nitrogen. In some cases the specimens were dipped into propane kept at −150 to −180 C. The aluminum plate with the frozen specimen was placed on a copper block, cooled in liquid nitrogen and transferred to the Edwards Pearse tissue dryer where the freeze sublimation occurred

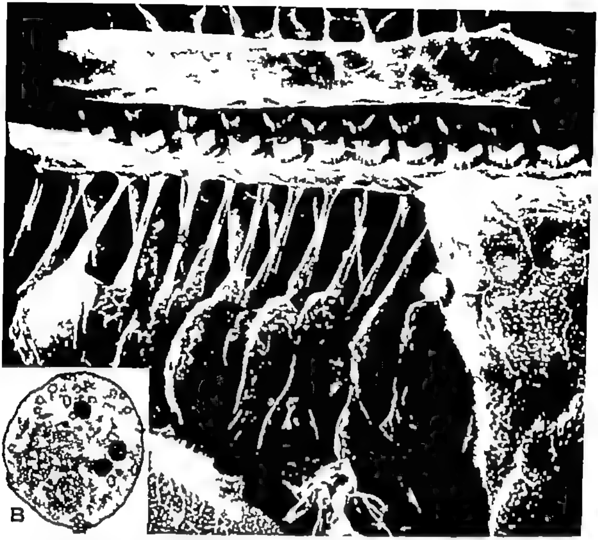

Fig 10 (A) The organ of Corti seen from the Hensen cell region towards the modiolus. Above the organ of Corti the tectorial membrane (*TM*) is seen. It has become slightly elevated from the hairs on the hair cells. The third row of Deiters cells send thin (star) phalangeal processes towards the surface. Fig 20 In these two specimens a fracture has been made through the spiral ganglion (*A*) and the spiral osseous lamina (*B*) In the ganglion cells (*Ggl*) the nucleus and the nucleolus are seen. The empty appearance of the nerve fibers (*N*) and the spongy structure of the ganglion cells are due to artefacts. In *B* the bundle of nerve fibers (N) is surrounded by bone. (A) ×4 500· (B) 800

The space between the first row of outer hair cells and the outer pillar cells (Nuel s space) is one of the intercellular spaces, all of which including the tunnel of Corti communicate freely with one another They are sealed off from the outside by the reticular membrane, Hensen s cells, the basilar membrane and the border cells (medially) As is evident from the scanning electron micrographs (Figs. 1 B 7 8 and 10) these spaces are, in fact one continuous space It is only in a conventional radial section (Fig 1 A) that it appears to be divided into several compartments. This space is filled with a fluid, the corti lymph (Engström 1960) and thus, the hair cells are bathed in this fluid.

Each outer hair cell is suspended from the reticular lamina and is supported by one Deiters cell. The phalangeal process extending from each Deiters cell to the surface of the organ of Corti forms a process, the phalangeal plate, between two sensory cells (Figs. 4 9 and 10) The phalangeal process is not associated with the same hair cell which is supported by its cell body beneath.

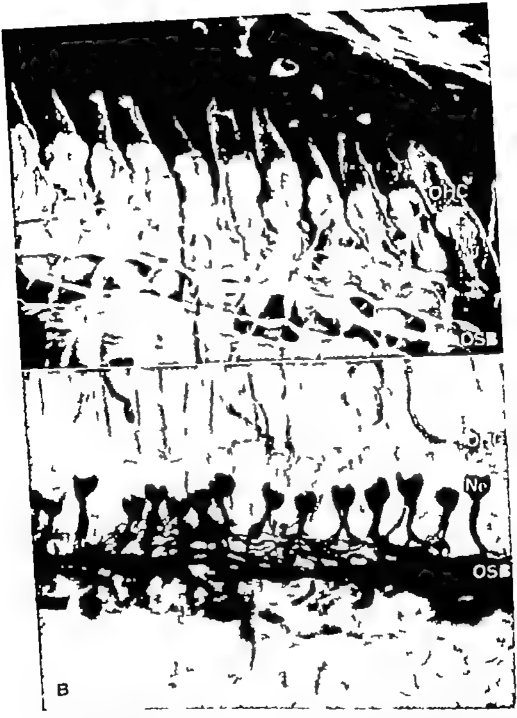

Fig 21 In A the organ of Corti has been opened and several outer hair cells (*OHC*) are seen from below At their bases nerve endings (*Ne*) and further down nerve fibres belonging to the outer spiral bundles (*OSB*) SEM 000 In B corresponding light microscopic picture of Maillet stained organ of Corti The black fibres and condensations are nerve fibres and nerve endings 930

Fig. 27. In B the Reissner membrane (*RM*) can be seen over the outer hair cells (*OHC*). This membrane consists of two layers of cells seen in A. The layer turned to the cochlear duct is provided with microvilli (*MV*), they have a rich endoplasmatic reticulum (*Er*) with ribosomes in moderate amount. Some mitochondria (*M*) are also found. These cells show indications of macropinocytosis. The mesothelial cells (*Mes*) are flat, bulging at their nuclei. They are rather rich in ribosomes. (A) 41 000, (B) 1 830.

Fig. 26. (A) The spiral tunnel bundle (*STB*), the inner spiral bundle (*ISB*) and several radiating tunnel fibres (*RTF*) from an opened organ of Corti. In B the corresponding components can be seen at higher magnification. Observe the swellings on the spiral tunnel bundle (*STB*). They correspond to the beads containing densely packed synaptic vesicles. SEM. (A) 3 400, (B) 12 200.

Rather there is a shift apically so that the phalangeal process helps to suspend the apical side of the hair cell adjacent to the one whose base rests on the Deiters cell itself (Figs. 4 9 and 10).

The surface of the organ of Corti is covered by a jelly-like filamentous structure the tectorial membrane which, originating from the spiral limbus, extends over the hair cells and as far as the Hensen cells (Fig 1). The longest hairs on each outer hair cell are in contact with the membrane (Kimura, 1966 Spoendlin, 1966) The free border of the tectorial membrane is fringed to form a marginal network which is in contact with the Hensen cells according to de Vries (1949) and Tonndorf et al. (1962) Lindeman et al. (1971) described a contact between the marginal fringe and the phalangeal processes of the third row of Deiters cells in kittens.

The hair cells are disposed in a highly characteristic pattern, as was recognized and illustrated in the second half of the 19th century by Retzius (1884) In most of the mammals studied, with the exception of man, the outer hair cells form three regular rows throughout the cochlea with occasional extra cells appearing in the second or third row and more rarely in the first row In man there are often four rows in the middle coil and five in the apical coil. The three rows of outer hair cells are situated lateral to the tunnel and separated from the one row of inner hair cells by the pillar cells, which also may have occasional extra cells (Figs. 1 A, 1 B, 3 and 4)

The upper surfaces of the sensory cells are suspended in the reticular lamina. The cuticular area of the upper surface of each cell is provided with sensory hairs or stereocilia which are arranged in a W-formation with the base of each W directed laterally (Figs. 5 12, 13 a and 14). The open angle of the W is wide at the base of the cochlea, and gradually diminishes toward the apex There are two other gradual changes which occur from the base to the apex of the cochlea, one being that the cuticular surfaces of the hair cells are kidney-shaped at the base, and become more oval at the apex, the other that the stereocilia increase in length. On each outer hair cell the stereocilia occur in three or more parallel rows of differing length. The outermost row is always composed of the longest hairs and the length decreases sharply in each succeeding row This is strikingly illustrated in certain of the scanning pictures, namely Figures 5 12 and 13

The inner hair cells differ conspicuously from the outer in that the W arrangement of the hairs is much less pronounced, the angle of the arms of the W being much more open than on the outer hair cells even at the base of the cochlea (Fig. 6). It approaches, but does not quite reach, 180 on the inner hair cells. The arrangement of the stereocilia in rows is very apparent, the longest again being on the outside with successively shorter hairs on the remaining rows There are more rows of hairs on the cells of the basal than on those of the apical coil (Figs. 15 and 16). The hairs of the innermost row are very short, becoming almost indistinguishable from the microvilli. In our study of the cat by scanning electron microscopy the tips of the stereocilia

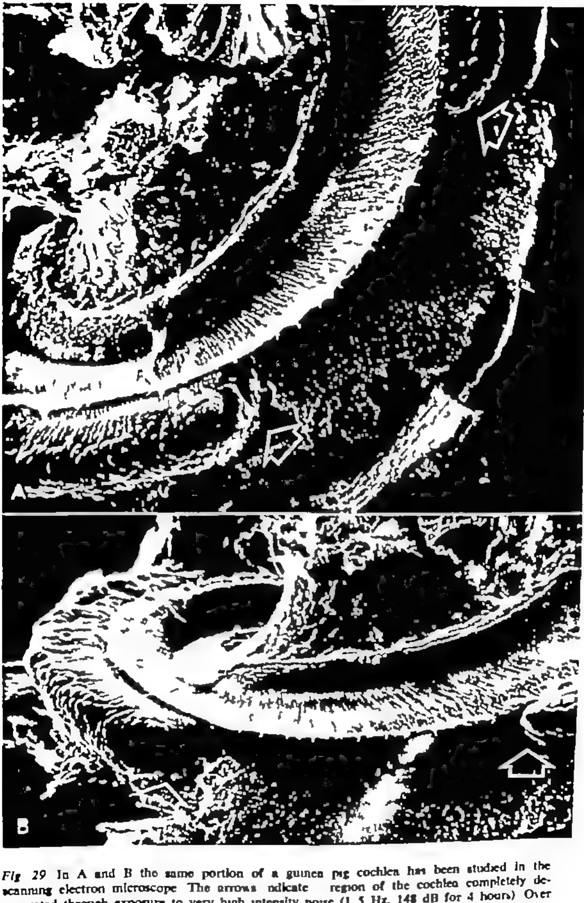

Fig 29 In A and B the same portion of a guinea pig cochlea has been studied in the scanning electron microscope The arrows indicate region of the cochlea completely degenerated through exposure to very high intensity noise (1.5 Hz, 148 dB for 4 hours) Over the organ of Corti the fibrillar tectorial membrane is seen Although the organ of Corti has disappeared completely in the injured area the tectorial membrane is still present. 195

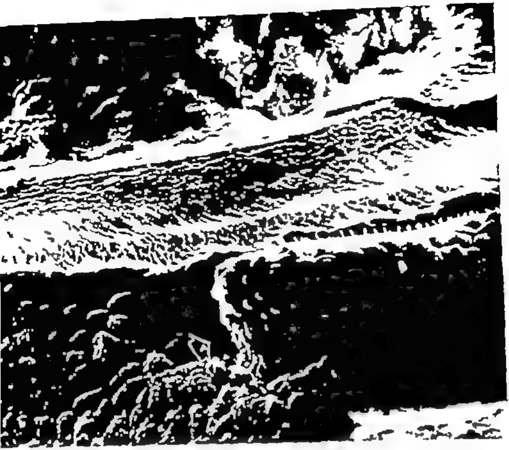

Fig 30 Detail from Fig 29 showing the sharp demarcation of the injured area. Observe that hair cells to the right of the damaged area are provided with hairs 400

of the inner hair cells are tapered asymmetrically with the exception of the longest row on each cell (Fig 15)

Several thorough ultrastructural investigations have come about because of interest in the functional role of the sensory hairs as it relates to stimulation of the organ of Corti. These include studies by Engstrom et al. (1962) Kimura et al (1964) Wersall et al. (1965) Kimura (1966) Spoendlin (1966) and Wersall & Flock (1967)

The kinocilium of the cochlear hair cell forms a subject of particular interest and has been reported variously by different authors to be present, not present, or modified The vestibular sensory cells are supplied not only with stereocilia, but also with one kinocilium each Observations by light microscopy (van der Stricht, 1908 Held, 1909 Kolmer 1927) indicated a similar situation of the hairs on sensory cells in the mammalian organ of Corti however recent studies by transmission electron microscopy have claimed that, while a kinocilium is present during fetal and very early postnatal life (Kikuchi & Hilding, 1965 a, b Kimura, 1966 Wersall & Flock, 1967), the sensory cells in the mature organ of Corti are devoid of this appendage. We have found that about one third

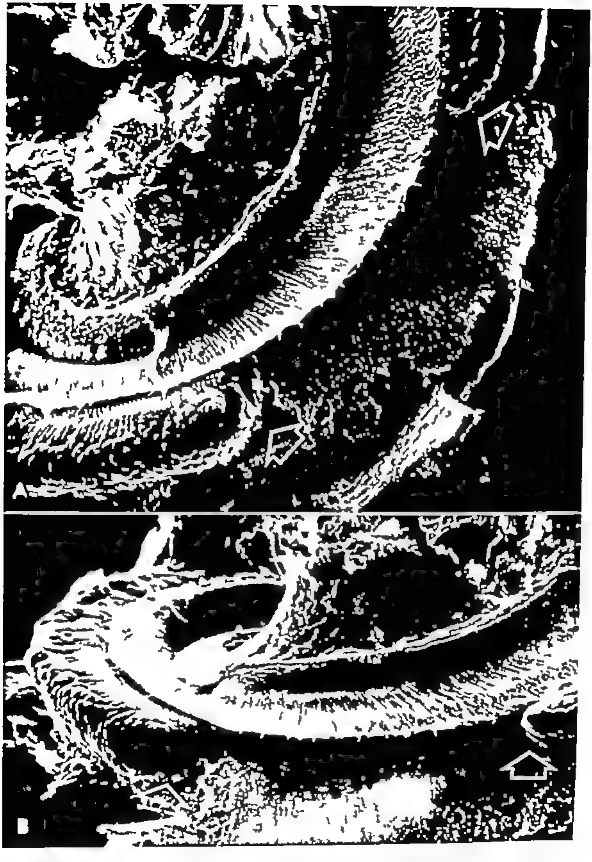

Fig 29 In A and B the same portion of a guinea pig cochlea has been studied in the scanning electron microscope The arrows indicate a region of the cochlea completely degenerated through exposure to very high intensity noise (1.5 Hz, 148 dB for 4 hours) Over the organ of Corti the fibrillar tectorial membrane is seen Although the organ of Corti has disappeared completely in the injured area, the tectorial membrane is still present. 195

Fig 33 Hairs on inner hair cells from the same cat as in Fig 3_. The general arrangement of the hairs is rather normal but the individual hairs have many irregularities especially at their outer ends. This can be found in normal specimens but is much more frequent in noise exposed animals. 10 600

of the outer hair cells in the middle coil of cynomolgus monkeys (Macaca fascicularis) of approximately four years of age have rudimentary kinocilium like processes (Figs. 13 18 B) Some few rudimentary kinocilium-like hairs can also be found on the outer hair cells of adult squirrel monkeys, which are neither as frequent nor as tall as those found in the cynomolgus monkey

A basal body believed to be a remnant of the kinocilium present during fetal life is found in the corresponding cuticle free region just under the surface of the sensory cell from which it may even protrude slightly The basal body has been found consistently in the guinea pig (Engström et al 1962 Flock & Wersäll 1962) and the protrusion can be demonstrated in scanning electron microscopy (Fig 12 D) On the other hand, Spoendlin (1966) has stated that the basal body is not to be found regularly in the cat It is difficult to be sure

Fig. 34. These four micrographs show different stages in sensory hair deformation. In A there are seen several giant hairs on an outer hair cell from a human cochlea. In B, also from an old human ear, a giant hair is seen protruding above the hairs of ordinary length. C and D. Guinea pig (upper basal coil), exposed to intense sound (4 000 Hz, 130 dB, 1 hour). There are slight irregularities on the individual hairs and in the arrangement of the rows of hairs. (A) 5 200, (B) 3 700, (C) 8 700, (D) 8 600.

A basal body believed to be a remnant of the kinocilium present during fetal life, is found in the corresponding cuticle free region just under the surface of the sensory cell from which it may even protrude slightly The basal body has been found consistently in the guinea pig (Engström et al. 1962 Flock & Wersäll 1962) and the protrusion can be demonstrated in scanning electron microscopy (Fig 12 D) On the other hand, Spoendlin (1966) has stated that the basal body is not to be found regularly in the cat. It is difficult to be sure

is also characteristic that the concentration of microvilli is denser close to cell junctions (Figs. 4–6, 15 and 16). The supporting cells of the reticular membrane have relatively few: the phalangeal processes of Deiters' cells showing them to be fairly evenly distributed. The phalangeal processes of the outer pillar cells have even fewer, almost exclusively close to the periphery of the cells. The inner pillar cell normally has very few microvilli. This is true also of the inner hair cells, although some of the stereocilia may be quite small, tending to merge with the microvilli in terms of size (Fig. 15). The dense distribution of the microvilli on the border cell (the cell closest to the inner hair cell on its modiolar side) is very striking (Figs. 4–6, 15 and 16). The same dense distribution is obvious throughout all coils and all species studied so far (guinea pig, cat, monkey, chinchilla, man). This can also be seen in the TEM (Fig. 16). The microvilli are less densely distributed on the inner sulcus cells, and again they are more numerous close to the cell borders.

In the human fetus, the microvilli of the organ of Corti are large and numerous, especially at the margins of hair cells. The supporting cells are also supplied with many microvilli, which appear to be more densely distributed in the fetal than in the adult man or animal (Figs. 17, 18 A and 19). In certain animals (e.g. mouse, cat, opossum) the cochlea is immature at birth. Specifically the cochlea of the newborn cat has microvilli which are larger and appear much more numerous than in the adult cat (Lindeman et al. 1971).

The afferent nerve fibers are supplied by bipolar ganglion cells whose soma lie in the spiral ganglion in the modiolus. The ganglion cells are distributed throughout Rosenthal's canal. It is possible to study these either by fracturing the frozen specimen (Fig. 20) or by direct dissection of the fixed specimen. These methods are as yet plagued by artefacts. In the dissected specimen, there is the additional factor of differential mechanical movement of the various elements in the structures which distorts the picture still more. Despite these difficulties, in Fig. 20 A the nucleus of the ganglion cell is clearly visible, and in the lower cell, even the nucleolus can be distinguished; however the myelinated nerve fibers appear to be composed of empty shells of myelin, the axis cylinders which should occupy them being absent, which is, of course, an obvious artefact. This is a problem which awaits resolution.

The peripheral dendrite of the afferent nerve runs through the osseous spiral lamina (Fig. 20 B) out to the organ of Corti where it ends as a series of small and sparsely granulated nerve endings on the hair cells (Fig. 22). The dendrite loses its myelin sheath before penetrating the medial attachment of the basilar membrane. The dendrites making contact with the inner hair cells are believed to take mainly a radial course, whereas the dendrites associated with the outer hair cells take a spiral course of varying, unknown distance in the spiral bundles within the organ of Corti (Figs. 21 A and B). Fibers from several nerve endings and from several outer hair cells are branches of a single dendrite. The pattern of innervation in the organ of Corti is extremely complex and is yet far from clarification. Spoendlin (1966) estimated, in the cat, that the majority of the

by scanning electron microscopy whether or not it is present because there are usually a few microvilli scattered in the region

The organ of Corti of a three month old human fetus is shown in Figs. 17 18 A and 19 A kinocilium like structure can easily be recognized on each sensory and supporting cell Moreover it is interesting to note that the W *arrangement of the hairs is not yet developed* The stereocilia are thickly and uniformly distributed over the surface of the cells, there are no rows, nor any indication of the staircase like differentiation of the cilia into regularly recurring diminishing lengths.

The conformation of individual stereocilia has often been observed in scanning electron microscopy however surface structures such as stereocilia and microvilli are quite susceptible to artefact and difficult to assess as to normality or abnormality We have frequently observed small blister like "blebs" on the surface of stereocilia as discussed in an earlier paper by the present authors (Engström et al 1970) The blebs, which have been seen with both transmission electron microscopy (Fig 14) and scanning microscopy (Fig 12) occur in animals regarded as normal (because they had not previously been exposed deliberately to noise) They occur more frequently in the squirrel monkey and cynomolgus monkey than we have seen in other mammals. In ears that have been exposed to damage noise or ototoxic antibiotics changes in the stereocilia are common and they may be quite pronounced (Figs. 32, 33 and 34) Lim (1971) described blebs like those mentioned above in normal guinea pigs, but they were more numerous in acoustically stressed ears. Similar formations were also seen by Ernstson (1971) in transmission electron microscopy of the hair cells of waltzing guinea pigs. He alluded to them as vesiculated malformations because of their high content of vesicles.

Another observation which may be akin to the blebs is that of small interconnections or bridges between individual stereocilia (Figs. 6 and 15) These were seen primarily on the inner hair cells of cats. The nature of the bridges is by *no means clear and they may be artefacts* however the artefact may correspond to real structure, although possibly altered by the fixation or the freeze drying which is part of the preparation. Much thinner strands around both cochlear (Kimura, 1966) and vestibular (Engstrom et al. 1972 in press) sensory hairs have been seen by transmission electron microscopy For example they may be condensations of macromolecular aglomerations on the outer unit membrane of the stereocilia They are more frequently seen in association with inner rather than outer hair cells which may be an indication that it is due to a compound or compounds more abundant around inner hair cells. It may be also that they are more easily seen when associated with inner hair cells.

A phenomenon which scanning reveals very *clearly is the distribution* of microvilli The sensory cells themselves normally display very few of these but the supporting cells especially the Hensen cells (Fig 8) and the border cells have a rich supply of microvilli on the surface facing the scala media It

The appearance of the tympanic layer of the basilar membrane is particularly striking in scanning electron microscopy. The arrangement of the cells is visible in light microscopy but the alignment in parallel, longitudinal rows is portrayed with clarity in scanning electron microscopy (Fig. 28).

THE APPEARANCE OF THE PATHOLOGICALLY ALTERED ORGAN OF CORTI IN THE SCANNING ELECTRON MICROSCOPE

The damaged organ of Corti has been examined by light/phase contrast microscopy and by transmission electron microscopy. The picture in light/phase contrast has been described in a number of experimental studies and need not be reviewed here. Less complete studies by TEM have yielded a certain amount of information. In particular it has further revealed some additional features of damage at the ultrastructural level, such as the Hensen bodies and nuclear changes (which have also been seen to a more limited extent in light/phase contrast studies). Scanning electron microscopy has now been applied to the study of the impaired cochlea, and has presented a picture which adds considerably to those yielded by the other two methods.

The first observations were made at low magnification and show the overall lesion in a way not seen before. A guinea pig was exposed to a high intensity pure tone of 125 Hz (148 dB 4 hours) and sacrificed two weeks later. The results are shown in Fig. 29 which shows two views of the same lesion, at the magnification indicated. The lesion is in the apical coil. It will be seen that there is a sharply limited area where the acoustic papilla is reduced to a simple cuboidal epithelium. This can be observed better in Fig. 30 which is a scanning micrograph of one edge of the lesion at higher magnification. Interestingly enough, the tectorial membrane is still in its position above the degenerated area, and, so far as can be told, normal in its conformation. The transitional zone seems very short between an area of complete degeneration of the organ of Corti and one of apparently intact sensory organ.

In an animal with less damage, sensory cells may be degenerated, but the general shape of the organ of Corti is still intact. A comparison between what may be seen in a scanning picture and a surface specimen is shown in Figure 31. Degeneration of receptor cells can be seen in both, but in the scanning picture the stereocilia can be seen as well, which becomes important in the circumstances described in the ensuing paragraph.

In experiments in which cats' audiograms were taken before and after exposure to intense sound, it was found on occasion that there was an apparent mismatch of audiometric loss and sensory cell population remaining: that is, there was a more profound hearing loss than seemed to be warranted by the cell loss. In a few cases, similarly exposed, SEM has revealed changes in the stereocilia of the hair cells. The changes consisted of fusion of stereocilia with reduction of size, or a complete disappearance of hairs (seen in the more basal

afferent nerve endings terminate on the inner hair cells, only about one tenth extending to the outer hair cells The innervation of inner and outer hair cells as well as the functions of the inner and outer hair cells are presently debatable, and it is therefore inadvisable to make any firmer statements about these relations.

The *efferent innervation* of the cochlea has its origin from the contralateral accessory olivary nucleus, from the homolateral main superior olivary nucleus and from the reticular formation The efferent bundle enters the cochlea via the olivo-cochlear anastomosis (Oort s anastomosis) runs in Rosenthal s canal forming intraganglionic spiral bundles, and passes through the osseous spiral lamina taking a spiral course It terminates as large nerve endings on both inner and outer hair cells (Figs. 21 B 22, 23 and 24) Efferent nerve fibers are found in a spirally running bundle inside the tunnel of Corti the spiral tunnel bundle (STB) (Figs. 25 and 26) The size of the nerve fibers in this bundle varies considerably as seen in transmission electron microscopy In scanning electron microscopy the appearance of swellings (beads") is very striking and it is possible that this explains some of the variation of caliber seen in transmission electron microscopy Thus the fiber size may in fact be more uniform than has been believed in the past (Figs. 26 A and B) and it may be only when a section is cut to include some fibers of normal size and some of the swollen fibers that one gets the mistaken impression that there is a considerable range of fiber size A number of the nerve fibers crossing the tunnel radiating tunnel fibers (RTF) pass through it, probably without branching or contact with the bundle (Fig 26 B)

The nerve fibers and the nerve endings which traverse or occupy a fluid filled space in the organ of Corti can be studied with minimal manipulation of the tissue but by dissecting the organ further observations can be made (Figs 6 20 21 and 23–26) The three-dimensional arrangement of nerve structures is very difficult to follow in light or conventional electron microscopy and here the scanning electron microscopy can be very helpful and adds much information The three methods may be compared in Figs. 21 22, and 23 The efferent nerve endings are larger than and partially enclose the smaller afferent endings (Figs. 21 and 22). The size of nerve endings diminishes as the apex of the cochlea is approached more closely The same phenomenon can be seen from medial to lateral, that is from OHC1 to OHC3

Reissner s (vestibular) membrane separates the scala media from the scala vestibuli being suspended between the spiral limbus and the vestibular crest of the spiral ligament. It consists of two layers of cells, one of ectodermal origin bordering the scala media and the other of mesodermal origin forming one border of the scala vestibuli (Fig. 27) The ectodermal portion is thicker than the mesodermal The two are separated by a thin basement membrane A few microvilli are seen on the cells of the ectodermal side In the scanning picture the bulging of the nuclei of the mesenchymal cells is prominent (Fig 27 B)

The appearance of the tympanic layer of the basilar membrane is particularly striking in scanning electron microscopy. The arrangement of the cells is visible in light microscopy but the alignment in parallel, longitudinal rows is portrayed with clarity in scanning electron microscopy (Fig. 28).

THE APPEARANCE OF THE PATHOLOGICALLY ALTERED ORGAN OF CORTI IN THE SCANNING ELECTRON MICROSCOPE

In the scanning picture the bulging of the nuclei of the mesenchymal cells is prominent (Fig 27 B)

at × 100 to 10 μ at × 10 000 This quality of the scanning electron microscope makes it a superb instrument for the study of surface topography

The study of the interior structure of cells by scanning electron microscopy so far remains a problem The process of preparing a specimen, dissection, fixing or freeze-drying, induces artefacts. The cytoplasm of a cell condenses and retracts the result is a non-homogeneous structure filled with apparent vacuoles (Figs 9 and 20) Great caution must be exercised in the interpretation of these pictures so that artefact is not taken to represent true morphological structure. For example in Fig. 20, if the hollow cylinders which represent the nerve fibers were to be interpreted literally one would conclude that the nerve fiber is a hollow tube, because only the myelin sheath remains more or less intact with fibrous looking material occasionally bridging across the gap that should represent the axoplasm. The axoplasm itself is gone. Likewise but less obviously the lacunae which are seen throughout the cytoplasmic and nuclear areas of the somata, might be interpreted as real structure which would be equally mistaken in the interpretation of Figs. 1 9 20, and 25 The wrinkles in the sensory cell seen in Fig 23 are artefacts in all probability and therefore potentially misleading Evidence of pronounced artefacts are also present in other early publications. Further experience in the techniques of preparation may reduce the artefacts to more manageable proportions however some of the artefacts have no apparent solutions as yet, and will yield only to new concepts of preparation.

The statement was made in the Introduction that scanning electron microscopy does not supplant either transmission electron microscopy or light/phase contrast microscopy The combination of scanning electron microscopy with one or the other seems to hold some promise of advancing our understanding of the ear and reducing the effects of artefact, or at least of changing the artefacts into a form with which we are more accustomed to dealing. Barber & Boyde (1968) for example, tried the combination of studying a specimen by scanning electron microscopy first and then embedding it for sectioning and study by transmission electron microscopy demonstrating surprisingly good preservation of the specimen in the transmission electron microscopy

The combination of light/phase contrast with scanning electron microscopy has also been shown to work quite well as applied to the cilia (Lindeman & Bredberg, 1972). Specimens first examined by light/phase contrast to obtain the advantage of mapping, were subsequently taken from under the cover glass and prepared for scanning electron microscopy and the two were compared. It was found that to all intents and purposes they were equally as good as those prepared first for light/phase contrast, showing only some flattening of cilia from the pressure of the cover glass.

The combination of light/phase contrast with transmission electron microscopy has also been shown to be quite feasible again going from the one to the other in that order cutting out small segments from known positions to embed This has the effect of overcoming to some extent the loss of overall

portion of the cochlea (Fig 34 C D) In the more apical portion a fusion and growth of the stereocilia to "giant" hair size may occur Similar changes have been observed in a sick cat (Fig 32) Figs. 34 A and B demonstrate changes in the stereocilia of elderly human subjects. It may be seen that there is gross dis organization of the hairs and formation of giant hairs. This is a subject without known exposure to noise but of course he may well have been exposed

Simple fusion of stereocilia has been described by Kimura (1966) and Kimura et al (1964) reported giant hairs in the human organ of Corti. Crysdale & Stahle (1971) observed severe pathology of the stereocilia following ultrasonic irradia tion of the cochlea in guinea pigs, and Stahle et al (1971) also described changes of the stereocilia after laser beam irradiation Ernstson (1971) observed similar structural modifications in the waltzing guinea pig associated with extrusion of cytoplasm from the cell into the stereocilia Fusion of stereocilia has been reported in the vestibular epithelium as a result of administration of ototoxic antibiotics (Duvall & Wersäll, 1963 Nagaba 1968 Lindeman 1969 Wersäll et al 1971) following X ray irradiation (Winther 1970) and in the waltzing guinea pig (Ernstson et al. 1969)

In view of these findings, described more extensively by Lindeman & Bred berg (1972) *it appears that fusion overgrowth and other changes in the* stereocilia constitute a non-specific reaction to a variety of noxious influences. This may indicate that damage to some basic structure or biochemical reaction has occurred which causes these changes. Which basic structure or what bio-chemical reaction this may be is an open question That the changes in the stereocilia may result in functional impairment is probable. The mechanical event which stimulates the sensory cell is generally conceded to be the shearing movement between the tectorial membrane and the sensory hairs, the longest of which are in contact with the membrane The pathological changes may interfere with this relationship in various ways. It could be at the level of contact which is certainly altered. Likewise it could be in an altered lever action of the stereocilia

The supporting cells, as well as the sensory cells responded to auditory over stimulation by an increase in the number and size of microvilli This was a phenomenon which was clearest in those ears showing the most pronounced changes in the sensory cells. Abundance of microvilli is generally associated with cells whose principal function is absorption Whether this increase fol *lowing acoustic overstimulation is a sign of increase in* absorptive functions of the supporting cells, or points to some other function is not clear

DISCUSSION

The obvious and striking advantage of the scanning electron microscope is the formation of a three-dimensional picture with good resolution and a good depth of field The field depth varies inversely with magnification from 1 mm

m $\times 100$ to 10 μ at $\times 10\,000$ This quality of the scanning electron microscope makes it a superb instrument for the study of surface topography

The study of the interior structure of cells by scanning electron microscopy so far remains a problem. The process of preparing a specimen, dissection, fixing or freeze-drying, induces artefacts The cytoplasm of a cell condenses and retracts the result is a non-homogeneous structure filled with apparent vacuoles (Figs 9 and 20) Great caution must be exercised in the interpretation of these pictures so that artefact is not taken to represent true morphological structure. For example in Fig. 20, if the hollow cylinders which represent the nerve fibers were to be interpreted literally one would conclude that the nerve fiber is a hollow tube, because only the myelin sheath remains more or less intact, with fibrous looking material occasionally bridging across the gap that should represent the axoplasm. The axoplasm itself is gone. Likewise but less obviously the lacunae which are seen throughout the cytoplasmic and nuclear areas of the somata, might be interpreted as real structure, which would be equally mistaken in the interpretation of Figs. 1 9 20 and 25 The wrinkles in the sensory cell seen in Fig. 23 are artefacts in all probability and therefore potentially misleading. Evidence of pronounced artefacts are also present in other early publications. Further experience in the techniques of preparation may reduce the artefacts to more manageable proportions however some of the artefacts have no apparent solutions as yet, and will yield only to new concepts of preparation.

The statement was made in the Introduction that scanning electron microscopy does not supplant either transmission electron microscopy or light/phase contrast microscopy The combination of scanning electron microscopy with one or the other seems to hold some promise of advancing our understanding of the ear and reducing the effects of artefact, or at least of changing the artefacts into a form with which we are more accustomed to dealing. Barber & Boyde (1968), for example, tried the combination of studying a specimen by scanning electron microscopy first and then embedding it for sectioning and study by transmission electron microscopy demonstrating surprisingly good preservation of the specimen in the transmission electron microscopy

The combination of light/phase contrast with scanning electron microscopy has also been shown to work quite well as applied to the cilia (Lindeman & Bredberg, 1972) Specimens first examined by light/phase contrast to obtain the advantage of mapping, were subsequently taken from under the cover glass and prepared for scanning electron microscopy and the two were compared. It was found that to all intents and purposes they were equally as good as those prepared first for light/phase contrast, showing only some flattening of cilia from the pressure of the cover glass

The combination of light/phase contrast with transmission electron microscopy has also been shown to be quite feasible again going from the one to the other in that order cutting out small segments from known positions to embed This has the effect of overcoming to some extent the loss of overall

orientation characteristic of transmission electron microscopy but so far it allows only for a sampling albeit a rational sampling The reverse order of study between scanning electron microscopy and transmission electron microscopy is not so feasible, inasmuch as the scanning electron microscopy artefacts are built into their subsequent study by transmission electron microscopy This is a problem that remains to be solved The procedure to be most useful, should produce in either order for either method in combination with scanning electron microscopy

Supporting Elements in the Organ of Corti

I. *Fibrillar structures in the supporting cells of the organ of Corti of mammals*

by Clarence Angelborg and Hans Engström[1]

During the last decade the interest in the structures of the inner ear has increased considerably. This interest depends upon several factors. The increasing knowledge of inner ear physiology has probably been the dominating factor but the development of new techniques for structural analysis has also played a major role. Transmission electron microscopy (TEM) has been the outstanding technique for structural analysis and has considerably enriched our knowledge of the organ of Corti. Recently an interesting new technique has become available in the form of scanning electron microscopy (SEM).

In the majority of the numerous articles written on the ultrastructure of the organ of Corti in recent years, the main interest has been devoted to the sensory cells and rather little has been said about the supporting elements in the cochlear duct. In relation to their studies on the inner ear fluids, Ilberg (1968), Ilberg & Vosteen (1969) among others made very few comments on the functional properties of the supporting cells. Duvall & Quick (1969) observed tracers in the Claudius cells after intrathecal injection of thorotrast.

During a series of experiments dealing with the passage of fluids between the different compartments in the cochlea, Angelborg (unpublished data) found evidence of high functional activity in several of the supporting cells. Cells regarded earlier as having a supporting function, gave evidence of pronounced phagocytic activity much more so than we had previously imagined. It also became evident that cellular damage could radically change the mode of action of the cells. Therefore further studies on the normal structure of the supporting cells have been started and these studies have been combined with experiments on the functional behaviour of the cells. In our first attacks on the problem we found a previously unknown principle in the arrangement of the tonofibrils in the pillar cells and Deiters cells. This contributed to our increased interest in the supporting structures of the organ of Corti.

Angelborg and collaborators are now carrying out studies on the structure and function of the supporting elements in the organ of Corti. The first paper contains a description of the normal anatomy of the pillar cells and Deiters' cells.

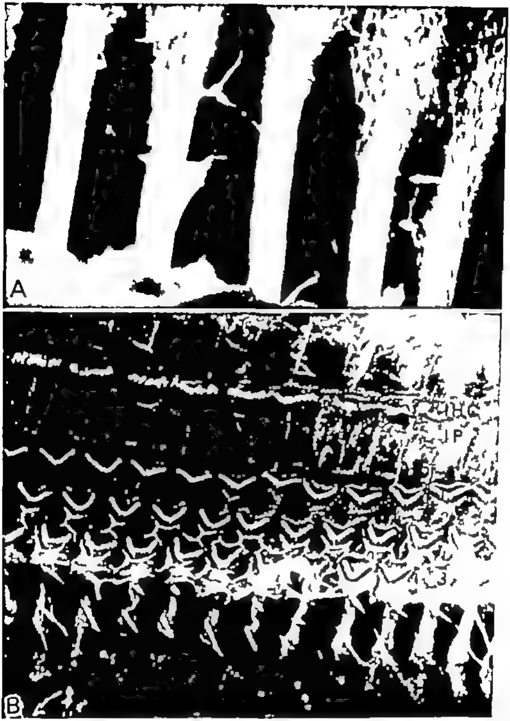

Fig. 1. (A) Outer pillars with nerve fibers passing between the cells. Squirrel monkey. SEM. (B) The organ of Corti as seen from the surface showing the heads of the inner pillar cells. Above these can be seen the heads of the inner hair cells and below three rows of outer hair cells. This portion is from the lower half of the cochlea and the angle between the hair rows is about 90 degrees. The picture also shows the outer edge of the third row of hair cells and the outermost row of phalangeal processes of the Deiters cells. Guinea pig. SEM.

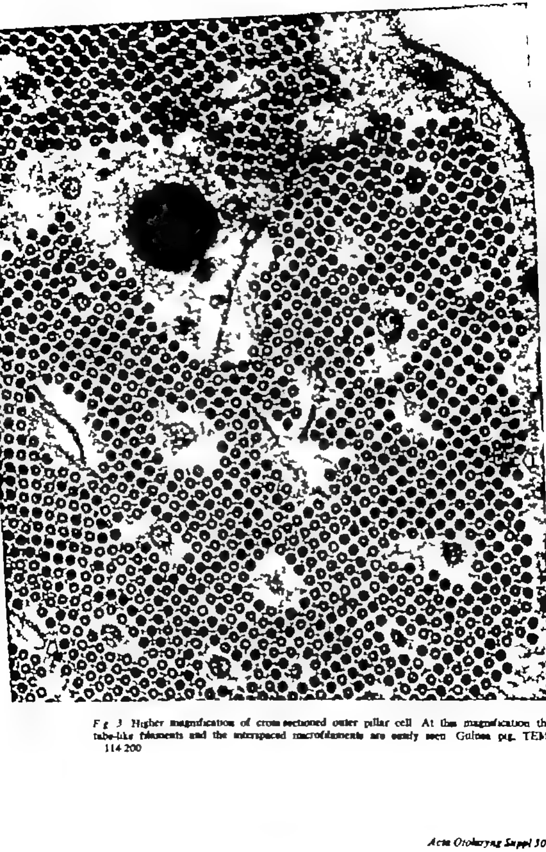

Fig. 3. Higher magnification of cross-sectioned outer pillar cell. At this magnification the tube-like filaments and the interspaced microfilaments are easily seen. Guinea pig. TEM × 114 200.

FIBRILLAR STRUCTURES IN THE SUPPORTING CELLS

The outstanding publication on the structure of the supporting elements in the organ of Corti was published in 1926 by Held and described the supporting cells and their inner structure. These cells are the inner and outer tunnel rods or pillar cells, the inner and outer phalangeal cells and the border cells axially of the inner hair cells. The first description of the pillar cells was given by Corti (1851) and Kölliker (1852) observed fibrillar structures inside the pillar cells. In a series of publications these cells were then described by different authors and Retzius (1884) presented beautiful illustrations of the supporting cells and their relations to the sensory cells and to the basilar membrane.

In each pillar cell (Pfeilerzell) Held describes a "footplate" adhering to the basilar membrane, a "middle-portion" and "head portion" In the inner pillar this last part forms a head plate" and an "Innenschabel" which enters between two inner hair cells, forming a triangular extension from the head portion. The outer pillar cells reach the surface outside the inner pillar head plate with an "oarshaped" plate (Ausenruder) which contributes to the forma tion of the surface of the organ of Corti and forms contact with the first and second row of outer hair cells

The middle portion of the inner pillar is rather flat and in the narrow spaces between individual cells, nerve fibres pass from the inner spiral bundle region to the tunnel and to outer hair cells. The middle portion of the outer pillar is more cylindrical (Fig 1 A) and contains large numbers of fibrils which are densely packed so that they form a fiber rod (Faserstab Held, 1926)

In many mammals and especially in rodents, the head portion contains a head inclusion or head body (Kopfeinschluss, Joseph 1900 Kopfkörper Held, 1926) This inclusion is rather electron dense The basal portion of both inner and outer pillars contains a similar substance forming the "basal cone" (Basal körperchen Held) (Fig 7) Held and others regarded this cone, which may have a varying height as a reinforcement for the anchorage of the tonofibrils. During the years there have been many descriptions of the supporting cells. Electron microscopy was introduced to these studies by Engstrom & Wersäll (1953) who gave a description of the cells and found tonofibrils with a diameter of around 200 A. These fibrils could be followed for a long distance inside the pillars and it was postulated that they reached from the base of the pillar to the top where they took part in the formation of the reticular membrane

Further information regarding the tonofibrils came in 1967 in a study by Iurato He found that they consisted of protein and that in the rat they had a diameter of 215 A and formed a cuboid lattice having a periodicity of 420 A. He found in the densely packed regions 570 filaments per square micron in outer pillars, while the density was lower in inner pillars Iurato compares the tonofibrils with the filaments of different plants and animals cells, described "as cytoskeletal structures associated with the maintenance of highly asymmetrical cell shapes" Iurato also found a different number of tonofibrils depending upon

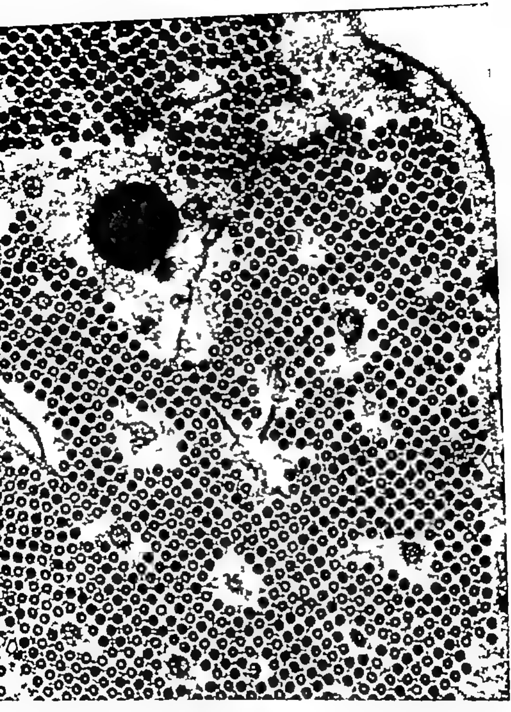

Fig 3 Higher magnification of cross-sectioned outer pillar cell. At this magnification the tube-like filaments and the interspaced microfilaments are easily seen Guinea pig TEM ×114 200

FIBRILLAR STRUCTURES IN THE SUPPORTING CELLS

The outstanding publication on the structure of the supporting elements in the organ of Corti was published in 1926 by Held and described the supporting cells and their inner structure These cells are the inner and outer tunnel rods or pillar cells, the inner and outer phalangeal cells and the border cells axially of the inner hair cells. The first description of the pillar cells was given by Corti (1851) and Kölliker (1852) observed fibrillar structures inside the pillar cells. In a series of publications these cells were then described by different authors and Retzius (1884) presented beautiful illustrations of the supporting cells and their relations to the sensory cells and to the basilar membrane

In each pillar cell (Pfeilerzell) Held describes a "footplate adhering to the basilar membrane a "middle portion" and head portion" In the inner pillar this last part forms a "head plate" and an "Innenschabel" which enters between two inner hair cells, forming a triangular extension from the head portion The outer pillar cells reach the surface outside the inner pillar head plate with an "oarshaped" plate (Ausenruder) which contributes to the formation of the surface of the organ of Corti and forms contact with the first and second row of outer hair cells.

The middle portion of the inner pillar is rather flat and in the narrow spaces between individual cells, nerve fibres pass from the inner spiral bundle region to the tunnel and to outer hair cells The middle portion of the outer pillar is more cylindrical (Fig 1 A) and contains large numbers of fibrils which are densely packed so that they form a fiber rod (Faserstab Held 1926)

In many mammals and especially in rodents, the head portion contains a head inclusion or head body (Kopfeinschluss, Joseph, 1900 Kopfkörper Held 1926) This inclusion is rather electron dense The basal portion of both inner and outer pillars contains a similar substance forming the basal cone" (Basalkörperchen Held) (Fig 7) Held and others regarded this cone which may have a varying height, as a reinforcement for the anchorage of the tonofibrils. During the years there have been many descriptions of the supporting cells. Electron microscopy was introduced to these studies by Engström & Wersäll (1953) who gave a description of the cells and found tonofibrils with a diameter of around 200 Å These fibrils could be followed for a long distance inside the pillars and it was postulated that they reached from the base of the pillar to the top where they took part in the formation of the reticular membrane

Further information regarding the tonofibrils came in 1967 in a study by Iurato He found that they consisted of protein and that in the rat they had a diameter of 215 Å and formed a cuboid lattice having a periodicity of 420 Å He found in the densely packed regions 570 filaments per square micron in outer pillars, while the density was lower in inner pillars. Iurato compares the tonofibrils with the filaments of different plants and animals cells, described as cytoskeletal structures associated with the maintenance of highly asymmetrical cell shapes" Iurato also found a different number of tonofibrils depending upon

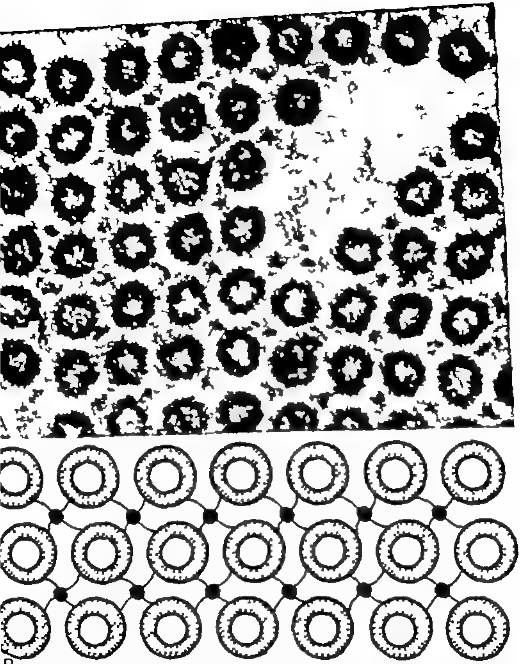

Fig 5 (A) Tube-like and solid filaments in an outer pillar cell Guinea pig EM × 440 000 (B) A schematic drawing of the arrangement of the tube-like filaments and the microfilaments The picture also shows some of the macromolecular bonds between the two different kinds of filaments It is also common to find two microfilaments in each interspace

Fig. 7. Base of an inner pillar cell resting on the basilar membrane. The basilar core can readily be observed and some of the tonofilaments are enclosed by the cementlike structure. A majority of the fibers start around the cone-like formation and there is also large number of mitochondria in this region. T the right of the base of the pillar can be seen the nerve fibers belonging to the inner spiral bundle. Squirrel monkey. TEM. 11 000

(C) Section at right angle to Fig. 6 A. To the left an outer hair cell and to the right Deiters' cell. Inside the Deiters cell few tubo-like filaments are on their way up to the cup-shaped part of the cell. They form a reinforcement that is attached to the sensory cell. Here we also can find tendency to cementlike formation. Squirrel monkey. TEM. (A) 134 000 (B) 60 000 (C) 45 000

Fig 6 (A) The junction between an outer hair cell and a Delters cell. The microfilaments are seen between the plasma membrane of the Delters cell and the tube-like filaments and also between the individual tubular filaments. (B) Longitudinal section through an outer pillar cell showing the parallel arrangement and dense packing of the tubular filaments.

section of the reticular lamina which surrounds the first row of outer hair cells.

In the outer pillars the filaments also originate in the basal cone where they have their origin in a wide area. The fibrils then become densely packed in the middle portion (Figs. 2, 3, 5) where they are arranged with almost geometrical regularity. In the head portion they fan out again and insert into the head inclusion and penetrate towards the outer hair cells where they participate in the formation of the reticular lamina. It was stated earlier that the filaments had a tubular nature and in the 60 A thick wall there is indication of some kind of denser sub-unit (Fig. 5) the nature of which we have not been able to discover. Each tubule runs for a long distance, presumably from the basilar membrane region to the reticular lamina. The arrangement of the tonofibrils at the base and in the head region indicates that they have an important function for mechanical reinforcement.

Beside and between the tubular tonofilaments there is a second system of microfilaments with a thickness of around 60 A. These filaments are much more numerous in certain parts of the pillars. In the central densely packed part of the middle portion of the outer pillars they are seen interspaced between the tubular filaments as seen in Figs. 3, 4 and 5 and in the schematic figure. These long microfilaments are provided with some molecular bonds which connect them to the tubular filaments. As far as we can find they run in the same manner as the tubular filaments presumably from base to top. The microfilaments follow close to the tubular filaments where they diverge at the top and base. The solitary fibrils diverging at the basal cone seem to retain a rather constant distance from a nearby tubular filament.

In the inner pillars we also find both the tubular filaments and the microfilaments and in those regions where the tubuli are closely packed the arrangement resembles that of the outer pillars. In certain areas where the arrangement of the tubular tonofibrils is less dense and at the periphery of the bundles of tubules, considerably more microfilaments than tubuli can be found.

In the Deiters cells the same two kinds of filaments are found. They begin at the basal end of the Deiters' cells in the small cementlike cone found close to the basilar membrane. In the dense thin columnar bundle of tubular tonofibrils seen in the lower part the thin microfilaments are interspersed between the tubules in the same manner as in the pillar cells. Close to the hair cell bases where some of the tubular tonofibrils form a cupshaped reinforcement they form a single layer of microfilaments between the plasma membrane and the tubular filaments. A few, usually two, microfilaments are also seen between the individual tubules (Fig. 6). At the outer hair cell bases the microfilaments are thus much more numerous than the tubular filaments. In the guinea pig we have found the relation to be 5 : 1 in some regions we have counted. We have not studied tonofilaments in the inner phalangeal cells or in the border cells.

We have observed, as stated previously, two systems of tonofilaments with different structures and presumably different properties. The structural organiza-

the age of his animals (rat) In the young rat there were about 2 500 filaments per pillar in the basal coil, 2 000 in the middle coil and 1 000 in the apical coil. In the adult rat he found 3 000–4 000 per pillar in the basal and middle coils and 1 500–2 000 per pillar in the apical whorl

Smith & Takasaka have recently (1971) given a description of the supporting cells in different animals In mammals they found tonofilaments or microtubules approximately 230 Å in diameter with thickened walls. They found that the tubule extended from the basal end of each pillar to the surface of the organ of Corti They also observed that the single units are bound together by some material and regarded this to be of importance for the strength of the supporting structures.

The Deiters cells *contain similar tonofilaments and occasional fibrils have* been observed *in inner phalangeal cells and border cells (Held, 1926) The fila*ments reach the surface of the organ of Corti where they take part in the formation of the reticular lamina. The word *lamina reticularis* was established by Kölliker (1852) and it is now widely used to describe the reticular lamina formed at the surface of the organ of Corti. It consists of supporting cells and their tonofibrillar structures and also a dense fine granular reinforcement found outside the hair cells into which the tonofibrils insert This granular structure seems to be of the same structure in the basal cones of the pillar cells and in the region where the tonofibrils of Deiters cells extend from the basilar membrane The resemblance to the head inclusions and to the reinforcements around the hair cells is also very evident. It is probable that they all form a kind of cementlike substance for the anchorage of tonofilaments at the basilar *membrane and at the surface of the organ of Corti In some animals a thin* layer of a similar substance can be found close to the bases of outer hair cells where some tonofibrils also insert forming a cup-shaped support for the hair cells.

In relation to an extensive study of the structure and function of the supporting cells carried out by Angelborg we had reason to study the tonofilaments of the supporting cells described above. We found that *both pillar cells and Deiters cells contain two different kinds of filaments* in the animals we have studied (guinea pig squirrel monkey cat, chinchilla and rat)

The most prominent filament is of a tubular nature In the middle coil of young guinea pigs they number about 2 400 and in the squirrel monkey they were counted in three adjacent pillar cells as *1 226 1 315 1 463 We have studied* them very closely in the guinea pig and squirrel monkey In the middle coil of the guinea pig (Figs. 2 3 4 5) they have an outer diameter of approximately 275 Å They are tubular in form and they have a wall thickness of around 60 Å In the inner pillars they are slightly irregularly arranged They start at the basilar membrane region in the cementlike substance of the basal cone which often has a lighter center and a denser outer portion They then become more densely packed in the middle portion and in the head they *fan out to the* reticular membrane close to the inner hair cells and *the outer pillars. But many* filaments also run over the heads of the outer pillars to become part of that

Stria Vascularis

by Jerome O. Sugar[1] Hans Engstrom and Jan Stahle[2]

INTRODUCTION

The vascular supply of the inner ear has been the subject of many investigations during the past century. One area in particular the vascular stria has claimed the interest of numerous researchers during this period. This region of the membraneous labyrinth has been described in numerous papers with the use of many different injection and staining techniques.

The stria vascularis was first observed by Corti (1851) and also described by Eichler (1892), who used india ink to show its vessels. In 1894 Siebenmann used Prussian blue to demonstrate the stria. Shambaugh (1903) described the stria vascularis as well as other capillary areas in the ear. Nabeya (1923) used Prussian blue, Smith (1951) used the benzidine method and lead chromate and Axelsson (1968) who used Prussian blue are among some of the more recent investigators of the capillary area in the lateral cochlear wall. Axelsson's study stands out among the more recent papers for its thoroughness in documenting the basic vascular anatomy of the cochlea in the guinea pig and in man. This recent paper meant, among other things, to bring order to the maze of terminology used in reference to the vascular channels of the cochlea.

The use of transmission electron microscopy in describing the ultrastructure of the stria vascularis was pioneered by Engstrom et al. (1955). Since then Smith (1957) Hinojosa (1966) and Kimura (1970) are among the many authors who have added greatly to our fundamental knowledge of the fine structure of this tissue.

In all the investigations of the stria vascularis done by light microscopy the problem of reproducibility of results and easiness of methodology stands out as being a constant problem. Smith (1954) observed in her human material that there was "considerable variation in distension of the vessels" with use of the benzidine staining method. Axelsson attempted in his monograph to bring an element of constancy to his preparations by only using the Prussian blue injection technique. In his study there was a constant problem of filling the stria capillaries. Thus Axelsson pointed out that in the guinea pig, "a common exception was the stria vascularis where small parts of the capillary net often were uninjected". In his human material, "the stria vascularis and the capillary region in the spiral lamina proved particularly difficult to fill completely".

tion of the pillars and the Deiters cells indicates that they are provided with a very well developed mechanical reinforcement system. The two systems of fibrils are anchored at their basal ends in a cementlike substance closely attached to the basilar membrane They are also bound together by as yet unidentified macromolecular interconnections. At the heads of the pillars the head inclusions form insertions for filaments. These form an important part of the reticular lamina in which they insert close to the outer and inner hair cells. In the basal portion of the cochlea the border between the outer pillar cells and the basilar membrane is often corrugated or irregular This presumably indicates a special differentiation for increased adherence (Fig 7)

SUMMARY

The pillar cells and the Deiters cells in the organ of Corti of mammals studied contain two kinds of tonofilaments bound together by macromolecular bonds In the squirrel monkey and guinea pig some filaments have a thickness of 275 Å and are tubular The tubular wall has a thickness of 60 Å We recommend that they should be called *tubular filaments.*

The other filamentous structures which we would name *microfilaments* have a diameter of 60 Å The microfilaments appear solid in our specimens and like the tubular filaments they are quite long. We believe they reach from the basilar membrane to the reticular lamina

A description is given of the fibrillar arrangement which indicates that the fibrils have a function of mechanical reinforcement.

Finally it is evident that if we are going to evaluate minor changes in the inner ear under the influence of damaging factors a good knowledge of the normal components is imperative.

Stria Vascularis

by Jerome O Sugar[1] Hans Engström[2] and Jan Stahle[2]

INTRODUCTION

The vascular supply of the inner ear has been the subject of many investigations during the past century One area in particular the vascular stria has claimed the interest of numerous researchers during this period. This region of the membraneous labyrinth has been described in numerous papers with the use of many different injection and staining techniques.

The stria vascularis was first observed by Corti (1851) and also described by Eichler (1892) who used india ink to show its vessels. In 1894 Siebenmann used Prussian blue to demonstrate the stria. Shambaugh (1903) described the stria vascularis as well as other capillary areas in the ear Nabeya (1923) used Prussian blue Smith (1951) used the benzidine method and lead chromate and Axelsson (1968) who used Prussian blue are among some of the more recent investigators of the capillary area in the lateral cochlear wall. Axelsson's study stands out among the more recent papers for its thoroughness in documenting the basic vascular anatomy of the cochlea in the guinea pig and in man. This recent paper meant, among other things, to bring order to the maze of terminology used in reference to the vascular channels of the cochlea.

The use of transmission electron microscopy in describing the ultrastructure of the stria vascularis was pioneered by Engstrom et al. (1955). Since then Smith (1957) Hinojosa (1966) and Kimura (1970) are among the many authors who have added greatly to our fundamental knowledge of the fine structure of this tissue.

In all the investigations of the stria vascularis done by light microscopy the problem of reproducibility of results and easiness of methodology stands out as being a constant problem. Smith (1954) observed in her human material that there was "considerable variation in distension of the vessels" with use of the benzidine staining method. Axelsson attempted in his monograph to bring an element of constancy to his preparations by only using the Prussian blue injection technique. In his study there was a constant problem of filling the stria capillaries. Thus Axelsson pointed out that in the guinea pig, "a common exception was the stria vascularis where small parts of the capillary net often were uninjected" In his human material, "the stria vascularis and the capillary region in the spiral lamina proved particularly difficult to fill completely"

Mass (1969) was able to achieve extremely good results in filling the stria vascularis as well as the rest of the vessels in the cochlea, but the difficulty of his modified benzidine method prevents its routine usefulness.

The problem of achieving a constant, physiologic appearance of the blood vessels in the lateral cochlear wall prompted this present study Our two goals in the investigation were to demonstrate without fail the stria vascularis and the other blood vessels in the cochlea We also wanted to develop a method that would be simple to use and could be performed without destroying the usefulness of the surrounding tissues for transmission and scanning electron microscopy

This paper is a preliminary report about a method that can be started within minutes prior to sacrificing an animal. This is followed by a microdissection of the inner ear and when this is completed the blood vessels can be visualized within a few minutes The results are excellent, they are reproducible and the specimens can be made quickly with a minimum of technical details. In the preparations it is possible to survey the vascular anatomy of the inner ear in part or in toto

MATERIALS AND METHODS

Because of the various experimental variables that were investigated in deter mining the optimum conditions for demonstration of the vascular anatomy the method will be presented in an experimental section and a preferred method section

Experimental section

50 pigmented guinea pigs (150–300 g) of the same strain were used in the present study The animals were anesthesized by an intraperitoneal injection of Nembutal (Abbott Laboratories, Chicago Ill) 20 mg/kg The animals were shaved clean of hair on the ventral aspect of the mandible and neck. The area over the mandible was infiltrated with subcutaneous 0 5% Xylocaine® and an incision of approximately 6 cm was made in the region over the ventral aspect of the mandible. The external jugular vein was exposed and horseradish per oxidase (Type II Sigma Chemical Co Saint Louis Missouri) dissolved in saline, sterile water or 0 9% NaCl 5–20 mg/100 g was injected intraveneously using a 27 gauge Luer Lok needle The animals were allowed to survive between

30 seconds and $1\,^1/_2$ hours after injection of the horseradish peroxidase. They were then decapitated and their bullæ removed.

The stapes was lifted out, the round window perforated and the apex of the cochlea opened prior to circulation of the fixation fluid. The following fixations were tried. 2% glutaraldehyde in 0.2 M phosphate buffer pH 7.4 2.5% glutaraldehyde, pH 4.4 2.5% glutaraldehyde in 0.07 M Sörensen's buffer pH 7.4 2.5% glutaraldehyde in 0.1 M phosphate buffer pH 7.4 10% formaldehyde pH 4.5 10% formaldehyde with 30% sucrose, pH 4.7 The fixatives were introduced through the oval window and gently circulated throughout the cochlea. In addition fixative was perfused through the round window and the apex. After fixation the specimens were either left in room temperature from 2–24 hours or refrigerated for 2–4 hours. Next the ears were rinsed in sterile water saline or buffer and then left either in veronal, phosphate or Sorensen's buffer The desired ears, either whole or in selected portions were incubated in a medium of 3–5 mg of 3,3'-diaminobenzidine tetrahydrochloride (Sigma Chemical Co Saint Louis, Missouri), or benzidine, 10 ml of buffer (phosphate, Sorensen or Tris buffer) and 0.1 ml of 1–3% H_2O_2 freshly prepared from 30% H_2O_2. The incubation medium was changed every 10 minutes and if the whole cochlea was incubated the fluid was circulated. The time of incubation was between 10 minutes and two hours. After incubation the desired portion or the whole cochlea was rinsed three times in distilled water during a 45 minute period. The cochlea was then either dissected, or the freed pieces were mounted in glycerine or Zeiss Embedding medium (ind. 1.50). If Canada balsam was used for mounting the tissues were dehydrated. After fixation some specimens were decalcified for one week in either 5% nitric acid or EDTA and after rinsing in buffer processed as previously stated

Photography was done with a Zeiss Ultropak or a Wild microscope.

Preferred method

Guinea pigs are intraveneously injected with horseradish peroxidase dissolved in 1 ml of sterile water 15 mg/100 g body weight and are allowed to survive for 10 minutes The animals are decapitated and the bulla fixed with 2.5% glutaraldehyde in 0.07 M Sorensen's buffer for 4 hours at 0–4 C. The ears are rinsed in saline and then stored at 0–4 C in 0.07 M Sörensen's buffer with sucrose Prior to incubation, the specimens are transferred to veronal buffer This buffer is used as the medium in which to dissect out various parts of the cochlea

If the specimen is to be decalcified it is fixed in the glutaraldehyde fixative for 4 hours and decalcified in EDTA for one week, changing the EDTA daily

The incubation medium is made fresh prior to use and contains: 4 mg 3,3'-diaminobenzidine tetrahydrochloride, 10 ml of 0.07 M Sorensen's buffer and 0.1 ml of 1% H_2O_2 made fresh from 30% H_2O_2. The specimens are incubated in the medium until the desired color of the vessels is achieved. With portions of stria this usually takes 20 minutes, with the organ of Corti 15 minutes and

if decalcified material is used 1–2 hours. The medium is changed at least every 30 minutes or more often if the color of the solution becomes dark brown. The progress of the reaction is usually observed through a dissecting microscope.

The stria vascularis of squirrel monkeys was prepared for electron microscopy by fixation in glutaraldehyde-osmium or in 1.5% veronal buffered osmic acid for 2 hours at 0–4 C. The specimens were dehydrated in increasing concentrations of alcohol and were embedded in epon. Thin sections were cut on an LKB Ultrotome III with a diamond knife, stained with uranyl acetate and lead hydroxide. The sections were viewed in a Siemens Elmiskop I A electron microscope.

RESULTS

The blood vessels of the lateral cochlear wall are clearly seen with the use of the presently described horseradish peroxidase-benzidine staining technique. The entire vascular anatomy of the external wall of the scala vestibuli, scala media and scala tympani shows a rich pattern of darkly staining vascular channels. In all of our specimens we have observed a consistent and reproducible staining pattern of the vessels in the stria vascularis and the spiral ligament.

In the present report we will only report on some of the more outstanding features of the stria vascularis and the spiral ligament since previous authors have extensively dealt with these topics (Smith, 1954 Axelsson, 1968).

The apical turns are characterized by fewer radiating arterioles and a markedly narrowed stria vascularis (Fig. 1 A) The stria increases in width in the more basal turns Also in the basal coils there are well demarcated spirally running vessels along the stria's inferior and superior borders.

The vessel of the spiral prominence (VSSP) is also a constant feature It is supplied by wide diameter arterioles from the radiating arterioles (Fig. 1 B). Arterio-venous anastomoses (AVAS) are abundantly seen in the spiral ligament (Figs. 1 and 2) These "thorough fare channels appear to be the main network for shunting the blood from the arterial system to the venous circuit. They are also of great importance for the exchange of oxygen and fluid in the spiral ligament

We noted in animals which for control purposes received only saline injection and were processed in the routine manner for demonstrating the vascular channels a rather constant staining of the stria but not of the arteriolar and venous systems These specimens looked very similar to those obtained with the conventional benzidine procedure. The presence of endogenous heme proteins and peroxidase enzymes accounts for this result. However with the addition of injected horseradish peroxidase the results were far more consistant and the quality superior to those without the exogenous enzyme.

In many ways the staining process is like a photographic printing process where the desired darkness of the print may be controlled by the length of time in the developer In the same manner the desired color of the vessels may be

In recent studies Osaka (1971) Winther (1971) and Duvall (1971) have examined the ultrastructural appearance of capillary permeability in the cochlea with particular reference to the stria vascularis. These authors have used a modification of the method introduced for electron microscopy by Karnovsky (1967). It was Strauss (1959) however who introduced the use of intravenously injected horseradish peroxidase as a tracer substance for light microscopy. His extensive studies on the biochemistry of the horseradish peroxidase mediated benzidine reaction have provided a firm theoretical and practical background for the use of this technique in histochemistry.

The basic principle of the technique as used by Strauss, Karnovsky and Duvall and as introduced in this paper for light microscopy of the cochlear vessels is a single enzyme mediated reaction. Horseradish peroxidase is an enzyme (MW 40 000) which acts in catalytic amounts to amplify the basic benzidine reaction. The presence of one molecule of the enzyme can mediate the oxidation of many molecules of benzidine in the presence of H_2O to a blue colored compound which is most likely a salt of a quinhydrone like molecular compound and quinonediamine. The base which forms at high pH is a brown reaction product and is the substance responsible for the staining of the vessels in the present study. Strauss (1964 *a, b*) has studied several variables that can affect the formation of a blue reaction product, the effect of pH, the concentration of H_2O and benzidine, the time of incubation, the temperature, and the solvent used. Our own studies have shown that the formation of the blue product is not a necessary prerequisite for its effective use in vascular studies of the ear. In fact, because of the intensity of the brown or red-brown reaction product formed at higher pH and its ease of formation, this latter stain is in our opinion and for our purpose more desirable.

The uniqueness of the present method is that the factors which act in the formation of a brown reaction product are the same elements that are necessary to preserve the specimens for further electron microscopic work. The effect of an added water based buffer, the physiologic pH range, the temperature and the materials used in fixation all contribute significantly towards good fixation of the tissues for electron microscopy and the optimum formation of the benzidine reaction product. Furthermore the brown color is more stable than the benzidine bl e product and does not require stabilization by nitroprusside as does the latter product. The action of osmium tetroxide on the brown substance is no hindrance to the use of this method.

In our studies we have seen that even without injection of the enzyme the reaction product appears to be found. Although the color and intensity of this reaction is not as sharp as the enzyme mediated one, it is nevertheless a well recognizable phenomenon. We have in fact used this endogeneous reaction much as Smith (1954), Mass (1969) and others to show the vascular supply when it was not possible to inject experimental animals.

The problem with the endogeneous reaction is its dependence upon the presence of erythrocytes. Romeis (1948) in his biochemistry text instructs the investigator

altered by varying the time the specimen is in the incubation medium The presence of the injected enzyme catalyzes the oxidation of many molecules of the diaminobenzidine to the colored reaction product. The appearance of the reaction product is thus not solely dependent upon the filling of the vascular system with erythrocytes. The colored reaction product may be seen inbetween single erythrocytes in the vessel lumen (Fig 1)

Our present efforts have also shown that the injected enzyme is stable to EDTA decalcification but not to nitric acid decalcification We have decalcified over 20 ears using this EDTA method and have subsequently shown the vascular pattern within the bony structures. The incubation time after decalcification is longer but the quality of the resultant reaction product is equal to the stain achieved in nondecalcified specimens

A rather striking feature in our specimens is the large diameter of the capillaries of the stria vascularis (Figs. 1 and 2) These large diameters are dependent upon the time the specimen is stored after incubation. It has been our experience that within a few days the physiologic pattern of the stria vascularis is lost and shrinkage of the vessels becomes evident This result has also been noted in other specimens of surface preparation material noteably from the vestibular structures (Rosenhall personal communication) This change may be responsible for the difference in information regarding the dimensions of the stria capillaries in previous reports (Axelsson 1968) and the present one.

The explanation of this fact is of great interest In Axelsson s specimens the interior of the blood vessels only are stained With the present technique not only the blood but also the vascular wall is stained But even if we consider this fact the present technique seems to demonstrate blood vessels with a considerably larger volume The volume of the stria vessels has important influence on the blood flow Accurate information about the real diameter and volume is necessary The diverging results with different methodology points to another interesting fact If the different techniques give very great variations there is good reason to believe that the vessels of the stria also intravitally can vary in diameter to a considerable extent This problem has been attacked by some scientists but their results demonstrate only minor variations (Perlman & Kimura 1955 Lawrence 1971)

Our laboratory has been occupied for a long time with studies of the effect of ultrasound and laser on the inner ear It was a logical step to study the present technique in irradiated specimens Stahle and Sugar Sugar et al have started an extensive series of experiments combining these techniques. It has been shown to be easy to damage the stria both by ultrasound and laser and the staining technique has beautifully demonstrated the extent and nature of the damage The stria is affected in different ways depending upon the type of energy and the dose given Ultrasound and laser irradiation (Figs. 6 A and B) cause very interesting patterns of damage in the stria The progress of destruction and the persistent appearance of degenerated capillary strands (Fig 6 B) are easily observed by use of the present method

to completely fill the vascular system for an effective benzidine reaction. In Mass (1969) study he spent considerable surgical time dissecting and occluding the arterial and venous systems. This lengthy procedure may be indicated in some studies but we feel the easier intravenous injection of exogeneous enzyme is preferable. The pseudoperoxidase reaction of Krabisch & Fischel as cited by Mass is both lengthier in its fixation requirements and more time consuming in the incubation process. For these reasons as well as the ease of reproducibility and the preservation of the tissues for electron microscopy we favor the procedure reported here.

The release of histamine by the exogeneous peroxidase enzyme has been studied by Winther (1971). He concluded that in the guinea pig this immunological reaction does not occur. Duvall (1971) suggests that the appearance of pores in the stria vascularis and the presence of leukocytes 10–15 minutes after injection of horseradish peroxidase may point to a histamine or serotonin releasing role by the enzyme. Cotran & Karnovsky (1967) and Copley & Carol (1964) have also presented data which suggest the guinea pig may release a vasoactive substance after horseradish peroxidase injection. Osako (1971) found that injected histamine did not increase the permeability of stria capillaries when 0.1 mg to 0.4 mg was used but found a decreased penetration of reaction product when 2 mg or more was used. It is obvious that Winther's (1971) study which reports no histamine in the blood of horseradish peroxidase injected capillaries is at odds with other reports. For our purposes the release of histamine does not seem to be as important as it does in the ultrastructural studies. In terms of quantitative measurements it would be possible to correct for the histamine effect if it is further documented to occur.

It is hoped that the suggested procedure in the present study will not deter further investigators from modifying the method. Once the basic principles of the histochemistry are understood it is a simple task to adapt this easy reproducible method for any particular problem or experiment. In our own laboratory we are continuing our research into the usefulness of this method and hope that with modification it can be used in cadaver specimens.

SUMMARY

The blood vessels of the lateral cochlear wall in the guinea pig are demonstrated by means of modified benzidine reaction surface preparation technique using injected horseradish peroxidase. The ease and reproducibility of the method is stressed as well as the adaptability of the technique for various fixatives and buffers. The new technique is applied to studies of the stria in normal guinea pigs and to striae in animals irradiated by ultrasound and laser. In addition some ultrastructural characteristics of the stria of the squirrel monkey are presented.

Macula Utriculi and Macula Sacculi in the Squirrel Monkey

by H Engström, B. Bergström[1] and H. W Ades[2]

The vestibular sensory epithelia are recognized as the regions of primary importance for our perception of motion and of our position in space. In normal animals these epithelia react to small gravitational changes and certain of their sensory cells have been regarded for many years as a species of accelerometer Interaction of vision deep sensibility and vestibular function permits us to observe and register accelerations or change of position. In the basic study by Wersäll in 1956 we received the first comprehensive report on the structure of the vestibular epithelia and many later reports have verified his observations The new information on the structure of vestibular sensory cells stimulated further studies on the functional properties of these cells. Lowenstein (1959) and collaborators, Dijkgraaf (1962) Flock (1965) and collaborators (1962) and many others, contributed to the information about the physiological properties of the vestibular sensory cells. An important step in the understanding of the function of the vestibular maculae was the finding of Engström et al. (1962), who first reported a morphological polarization of the macular epithelia. A polarization of crista ampullaris had earlier been described by Lowenstein & Wersäll (1959) This was followed by studies by Flock (1964 1967) Spoendlin (1964) Lindeman (1969) and others, showing that the vestibular maculae had a structural as well as a functional polarization. That is, the sensory cells are structurally and functionally oriented in a specific direction over large areas. This polarization changes radically through nearly 180 in the region of the striola (cf Werner 1933 Lindeman, 1969) It has been found further that the striolae and the crests of the cristae have a characteristic population of sensory cells (Lindeman, 1969 Watanuki & Meyer z. Gottesberge 1971)

The vestibular sensory areas are found, one in each of the ampullae of the three semicircular canals, one in the macula sacculi, and one in the macula utriculi They are of fundamental importance for our sense of equilibrium and motion The sensory cells of the vestibular sensory areas are integrated into a functional system for orientation in space and for the perception of linear or angular acceleration. Normally the sensory cells are acted upon by small gravitational forces, but with the development of aircraft and space vehicles, the G forces to which the human vestibular system is exposed have been drastically

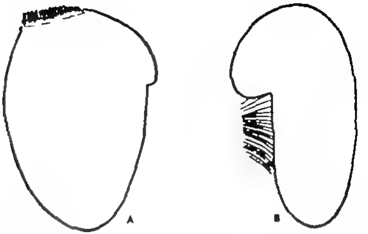

Fig. 1. Schematic drawing of (A) macula sacculi and (B) macula utriculi of guinea pig demonstrating the general form of the maculae.

as crystals formed postmortem. In all our fixed specimens the crystals have been characteristic in form (Fig. 2 B), but evidently we have to study living animals to ascertain their true form.

Orientation is a result of inputs of information from many receptors in both labyrinths. These receptors inform the central nervous system, eye muscle nuclei, cerebellum and spinal cord of modifications acting upon the peripheral sensory regions. Feedback systems in the central nervous system actively influence the peripheral sensory cells and nerve fibers. In case of severe damage to the peripheral vestibular system, several of its functional deficits can be compensated for centrally.

The form of the maculae in those mammals we have studied (guinea pig, squirrel monkey, cat, rabbit, chinchilla, rat) is essentially similar from one species to another. They vary in size but have in general the same appearance. The form can be seen in Fig. 1. Our findings are similar to those of Lindeman (1969) though the macula utriculi differs slightly from his. Exceptionally beautiful preparations have been made by Watanuki (1971).

The sensory epithelia of these two maculae differ very little, however, one important difference is that the orientation of the sensory cells in relation to the striola is reversed. This will be discussed further below.

The sensory epithelium consists of sensory cells and supporting cells, resting on a basement membrane. The maculae are innervated by the saccular nerve and the utricular nerve respectively (cf. Lindeman, 1969). The total number of sensory cells on the macula utriculi in man is 33 100, and the total number on the macula sacculi is 18 800 (Rosenhall, 1972). The total number of nerve fibers innervating these is 5 950 for the macula utriculi and 4 050 for the macula sacculi (Bergström, in manuscript). They have shown that in man the number of sensory cells as well as the number of nerve fibers is considerably

changed. Unexpected and dramatic reactions may occur during exposure to high or low gravitational forces which has led to an augmentation of interest in the structure and function of the vestibular system. Several publications on the morphology of the vestibular sensory epithelia have appeared from our group (Ades & Engström 1965, Engström 1970, Lindeman 1969). The present study, which is a direct continuation of our earlier studies on the inner ear, has taken up anew the morphology of the sensory regions of one mammal, the squirrel monkey. The reason for this is evident. The development of technique for ultrastructural research has now reached a point at which it is possible to make high quality electron microscopic studies with reproducible results. If we are going to find small alterations in these sensory regions after damage from ototoxic agents or overexposure to G forces, it is imperative to have a detailed background of information on the normal structure. The squirrel monkey has been chosen because it is a commonly used animal and it has an inner ear with a high degree of resemblance to the human inner ear (Spoendlin 1965). We have also used this animal widely in our experiments on the effect of noise or ototoxic agents on inner ear sensory cells.

A large part of this study will be devoted to a photomicrographic documentation of the structure of the vestibular sensory cells and their innervation, but attention will also be devoted to a description of the supporting cells. The innervation of the vestibular sensory areas in man has been the subject of a special study by Bergström (in press), who has made a careful quantitative analysis of the number of nerve fibers in the human vestibular nerve. He has found that there is a marked reduction of nerve fibers with increasing age which is in close agreement with the studies by Rosenhall (in press), also of this group, who has shown that there is a considerable reduction of sensory cells in the vestibular areas in elderly people. Thus, presbyacusis evidently is paralleled by an aging in the vestibular organ.

The vestibular labyrinth contains three semicircular canals in each ear, with the sensory epithelia on the cristae ampullares, and the utricle and saccule with the sensory cells located respectively in macula utriculi and macula sacculi (Fig. 1). Over the surface of the crista epithelium there is a gelatinous mass, the cupula, with a specific gravity close to that of the endolymph, while the maculae have over their surfaces a similar gelatinous mass containing calcite crystals or statoconia (Fig. 2 B), with a specific gravity of approximately 2.74. These crystals have been carefully described by several authors. Their composition varies in different species. In mammals they were originally described as composed of aragonite, but Brandenberger & Schintz (1945) and Carlström & Engstrom (1955) proved that mammals have calcite crystals. Lindeman (1969) observed sizes of crystals varying between 1 and 30 μ and he also described a distribution of crystals according to a specific pattern. This pattern was verified by Watanuki et al. (1971); however, Sasaki (1970) was not able to find any large crystals in living animals, but only gel-particles less than 0.1 μ long suspended in a protein solution. He regarded the statoconia described above

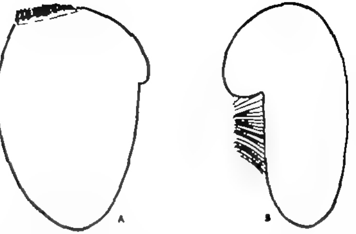

Fig 1 Schematic drawing of (A) macula sacculi and (B) macula utriculi of a guinea pig demonstrating the general form of the maculae

as crystals formed postmortem. In all our fixed specimens the crystals have been characteristic in form (Fig. 2 B) but evidently we have to study living animals to ascertain their true form

Orientation is a result of inputs of information from many receptors in both labyrinths. These receptors inform the central nervous system, eye muscle nuclei, cerebellum and spinal cord of modifications acting upon the peripheral sensory regions Feedback systems in the central nervous system actively influence the peripheral sensory cells and nerve fibers. In case of severe damage to the peripheral vestibular system, several of its functional deficits can be compensated for centrally

The form of the maculae in those mammals we have studied (guinea pig, squirrel monkey cat, rabbit, chinchilla, rat) is essentially similar from one species to another They vary in size but have in general the same appearance. The form can be seen in Fig 1 Our findings are similar to those of Lindeman (1969) though the macula utriculi differs slightly from his. Exceptionally beatuiful preparations have been made by Watanuki (1971).

The sensory epithelia of these two maculae differ very little however one important difference is that the orientation of the sensory cells in relation to the striola is reversed This will be discussed further below

The sensory epithelium consists of sensory cells and supporting cells, resting on a basement membrane The maculae are innervated by the saccular nerve and the utricular nerve respectively (cf Lindeman, 1969) The total number of sensory cells on the macula utriculi in man is 33 100 and the total number on the macula sacculi is 18 800 (Rosenhall, 1972) The total number of nerve fibers innervating these is 5 950 for the macula utriculi and 4 050 for the macula sacculi (Bergstrom, in manuscript) They have shown that in man the number of sensory cells as well as the number of nerve fibers is considerably

reduced with increasing age This paper however is concerned principally with the sensory epithelium and its innervation from the standpoint of structure.

As early as 1858 the vestibular sensory epithelia were observed and described by Schulze It remained for Retzius (1884) to describe them further and to make beautiful illustrations of ciliated cells in the epithelium He described cilia of different lengths on individual cells, and his text indicated a recognition that the length difference might be of functional importance

The first thorough description of the vestibular sensory cells waited until Wersäll (1956) was able to accomplish it, using the electron microscope In an extensive study on the structure and innervation of the epithelium of the cristae he described two kinds of sensory cells, type I and type II He further described their innervation and their supporting cells. Wersäll indicated also that the same types of cells could be found in the macular epithelium The principles of organization outlined by Wersäll have been verified by several later observers and little has been added however one important addition has been made and that is the double innervation of all inner ear sensory cells (Engström 1958)

Improvement in instruments and techniques have made possible a more detailed and accurate description of the ultrastructure of the vestibular epithelium A major step was made with the discovery of a structural polarization of the sensory cells on the maculae (Engström et al 1962 Ades et al. 1962 Flock 1964 Spoendlin 1964 Lindeman 1969) In connection with this, an interesting observation was the different structure of the striolar region The striola had already been described by Werner (1933) but his findings were not discussed much before Engström & Wersäll (1958) pointed out that the striolar region of the macula utriculi contains a larger number of the type I cells than do the extra striolar areas. Since then the subdivisions of the vestibular maculae have been carefully studied (cf Lindeman 1969 Watanuki 1972)

In summary then the present concept is that the vestibular maculae consist of receptors of type I and type II surrounded by supporting cells. The epithelium is innervated by myelinated nerves of varying caliber (Bergström in manuscript) There are in addition a fairly large number of non myelinated nerve fibers under the basement membrane (Wersäll 1956 Spoendlin 1965) Whether or not these also enter the sensory epithelium is as yet unknown

The cells of type I (Figs. 3 4 5 6) are flask shaped They have a cuticular surface which is provided with sensory hairs, a narrow neck region and a wider cell body around the nucleus The whole cell with the exception of the uppermost portion is enclosed in a nerve chalice which is the termination of a large caliber myelinated nerve fiber A nerve fiber may form separate chalices around several type I cells or it may form a single larger chalice which encloses several such cells. The chalice is surrounded in turn by supporting cells which extend from the basement membrane to the surface of the macula (Figs. 6, 7)

Each type I cell has a cuticular thickening at its surface (Figs. 7 15 16)

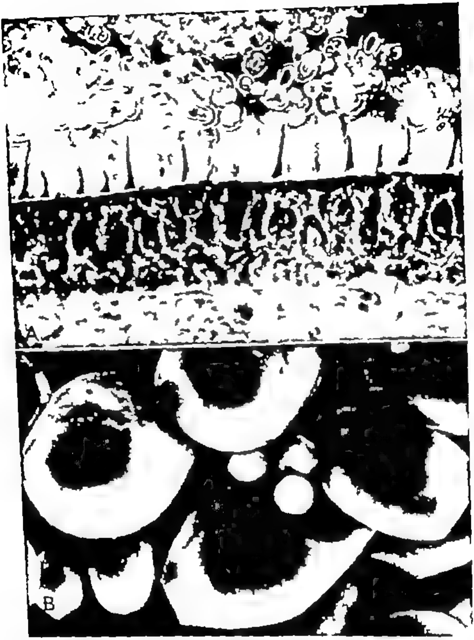

Fig. 2. A shows the general arrangement of the epithelium of macula utriculi in a squirrel monkey. Over the surface sensory hairs of different lengths on individual cells and above the hairs statoconiae. Improvement in instruments and techniques have made possible a more detailed and accurate description of the ultrastructure of the vestibular epithelium A major step was made with the discovery of a structural polarization of the sensory cells on the maculae (Engström et al 1962 Ades et al. 1962 Flock, 1964 Spoendlin 1964 Lindeman 1969) In connection with this, an interesting observation was the different structure of the striolar region The striola had already been described by Werner (1933) but his findings were not discussed much before Engström & Wersäll (1958) pointed out that the striolar region of the macula utriculi contains a larger number of the type I cells than do the extra striolar areas. Since then the subdivisions of the vestibular maculae have been carefully studied (cf Lindeman 1969 Watanuki 1972)

In summary then the present concept is that the vestibular maculae consist of receptors of type I and type II surrounded by supporting cells. The epithelium is innervated by myelinated nerves of varying caliber (Bergström in manuscript) There are in addition a fairly large number of non myelinated nerve fibers under the basement membrane (Wersäll 1956 Spoendlin 1965) Whether or not these also enter the sensory epithelium is as yet unknown

The cells of type I (Figs 3 4 5 6) are flask shaped They have a cuticular surface which is provided with sensory hairs a narrow neck region and a wider cell body around the nucleus. The whole cell with the exception of the uppermost portion is enclosed in a nerve chalice which is the termination of a large caliber myelinated nerve fiber A nerve fiber may form separate chalices around several type I cells or it may form a single larger chalice which encloses several such cells. The chalice is surrounded in turn by supporting cells which extend from the basement membrane to the surface of the macula (Figs. 6 7)

Each type I cell has a cuticular thickening at its surface (Figs. 7 15 16)

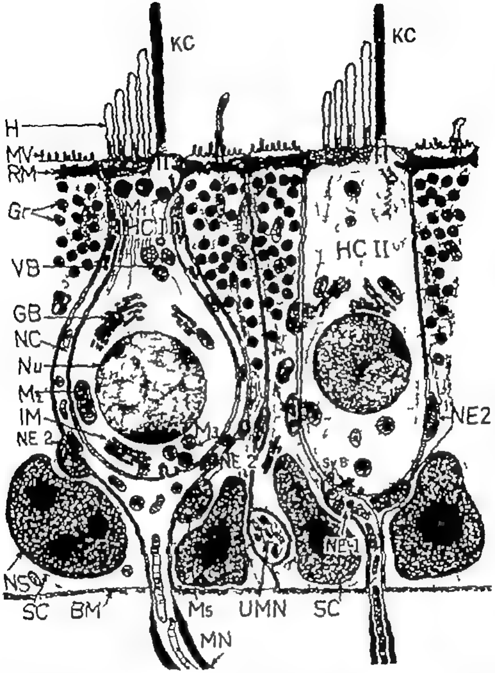

Fig. 3. Schematic drawing of the arrangement of the sensory cells in the vestibular epithelium. This drawing follows in many ways the principles described by Wersäll in 1956. The improved knowledge of the innervation pattern and synaptic structures, of intracellular filaments and of the arrangements of kinocilia on supporting cells should be noticed.

from which protrude a large number of cilia (Fig 16 17) The sensory hairs are of two kinds, one kinocilium and many stereocilia. The kinocilium is usually placed eccentrically with respect both to the stereocilia and the cell s surface (Fig 17 C) but variations on this are seen so that an occasional cell with a centrally located kinocilium is found (Fig. 17 D) The kinocilium is usually the longest of the cilia by a considerable margin. In the squirrel monkey it may have a length of up to 40 μ It is also the thickest of the cilia and the most conspicuous, and is characteristically formed on the well known principle of nine double fibrils surrounding a centrally located pair of fibrils. The central fibrils are not present throughout the whole cilium It is not uncommon to find abnormal kinocilia or double cilia or cilia with many fibrils (Fig 18 A B) Each kinocilium extends from the upper surface of the cell It has a neck portion (Figs. 16 17 B) with a length of about 0 20–0 25 μ and then the kinocilium proper (diameter approximately 0 25–0 30 μ) Inside the cell there is a typical basal body with triple fibers, and from the lower end there extend thin cross-striated fibrils (Spoendlin 1965 Afzelius & Franzén 1971) A centriole can be seen below the basal body (Fig 16) We have often observed that thin non-striated fibrils or tubules extend from the basal body region These fibrils (approximately 230 Å) can be seen in several of our micrographs (Figs 7 8) They extend through the neck portion to the lower part of the cell. Similar fibers have been found in the cochlear hair cells (Ilberg 1969 Engström & Ades, in press) Only the kinocilium is provided with a basal body The stereocilia which are the numerous sensory hairs are inserted with rootlets in the cuticular plate The stereocilia are arranged in regular rows at the surface of the cells (Fig 17 C) Their numbers seem to vary to some extent but they are of the order of 70–80 hairs. They have a varying length with the longest hairs close to the kinocilium gradually tapering off in length away from the kinocilium The gradual decrease in length is quite characteristic As already described the different length of the hairs was seen by Retzius (1884) but it was pointed out anew by Engstrom et al. (1962) The shortest hairs are somewhat thinner than the longer (Fig 17 C) The characteristic arrangement can be seen well in scanning electron microscopy (Engström 1970) The diameter of the thick stereocilia is fairly constant and is about 0 25 μ They have rootlets which almost penetrate the cuticular plate The hair proper having different lengths on the same cell may also differ between different cells This can be seen especially well with the scanning microscope The stereocilia are considerably thinner being 0 10–0 15 μ close to the cuticle The longest kinocilia and stereocilia are found on the ampullar crista while the kinocilia of the macula are usually less than 40 μ Vestigial kinocilia also appear on the supporting cells (Figs. 19 22) but are considerably shorter than those on sensory cells.

The diameter of the surface of the hair cells of type I is approximately 4 μ the thickness of the cuticle may vary but is usually about 1–1.5 μ The region in which the kinocilium is found has no cuticle. The cuticular plate consists of a finely granular or fibrillar material In the periphery of the cuticular

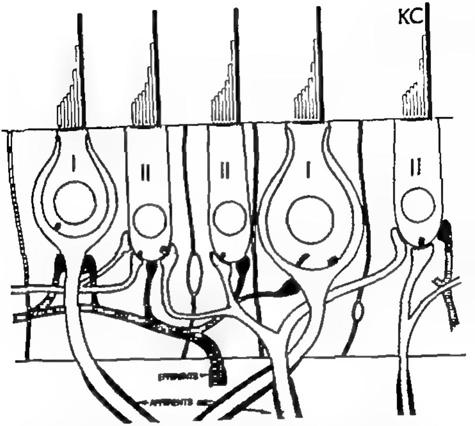

Fig. 5. Schematic drawing showing the arrangement of sensory cells and nerve fibers in macula. The myelinated fibers enter the sensory epithelium perpendicularly; they pass between the supporting cells and above the nuclear level many fibers form a nerve fiber layer parallel with the basement membrane. Some of the thick calibre nerve fibers retain their perpendicular direction to form nerve chalices around type I cells. *KC* is kinocilium. The stereocilia by its side are of diminishing lengths in a direction away from the KC.

---

plate is often found a thin layer of fibrillar nature, with denser lines (Fig. 21 B). It was seen by Friedmann (1968) and later reported by several authors. It is said to increase in vestibular sensory cells of man, suffering from Ménière's disease.

The infracuticular region contains a group of mitochondria, each one with a diameter of about 0.35–0.50 μ and a varying length, seldom over 1 μ. The mitochondrial cristae are densely packed. In this region of the type I cell we also find several vesicles or smooth profiles, a poorly developed endoplasmic reticulum with ribosomes, and one to a few multivesiculated bodies on the border of the supranuclear portion. On the border between the cuticle and the infracuticular regions, along the rim of the hair cell is found a ringshaped shelf formed by a reinforcement of high density (Figs. 20, 21 and 22). The shelf seems to support the cuticle in such a way that the cuticle rests on and is attached to it. The shelf itself is not quite continuous all the way round the cell, and is closely related to the fibrillar structures inside the supporting cells.

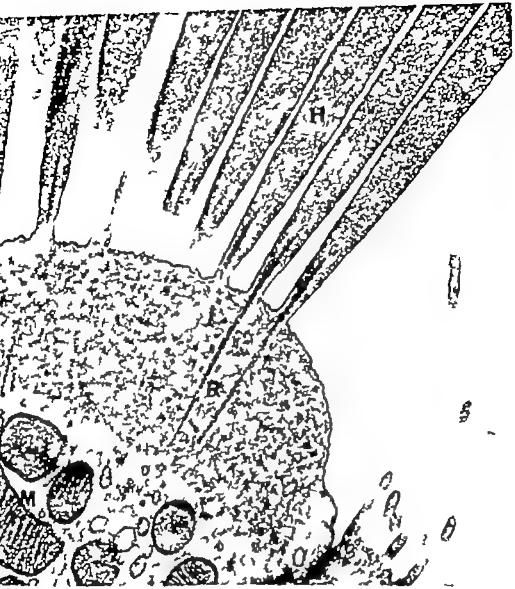

Fig. 15. The cuticular portion of a type I cell in the macula utriculi. From the surface sensory hairs (*H*) protrude. They are thinner close to the cuticle and become thicker peripherally. Each stereocilium has a denser central core best seen close to the cuticle and this core continues down into a tapering rootlet (*R*) which inserts in the cuticular plate. The infracuticular region contains mitochondria (*M*) with densely packed cristae. × 43 500.

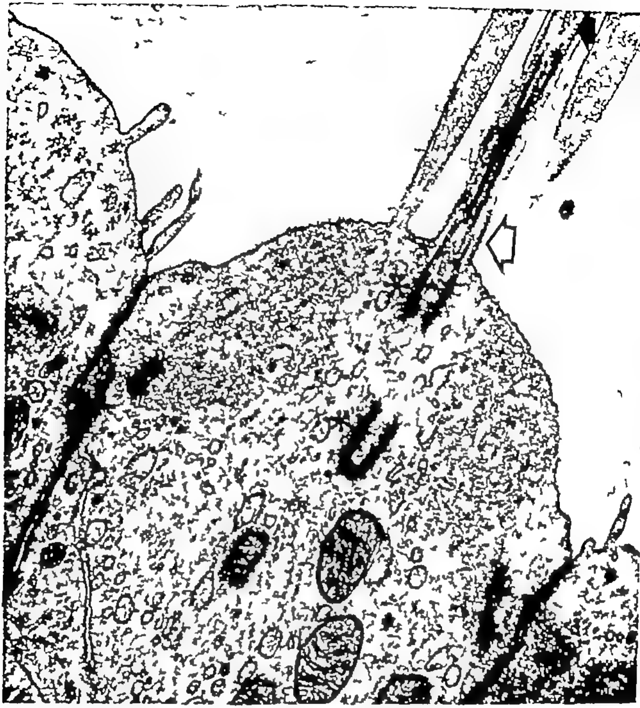

Fig. 16. Type I cell from macula utriculi with one kinocilium and two stereocilia. Below the basal body (star) a centriole (star) can be seen. The open arrow indicates the neck portion of the kinocilium with its spiral structure. The black arrow shows the region in the kinocilium where the central fibrils usually disappear and small granular structures appear. See also Fig. 17 A, B. × 51 000.

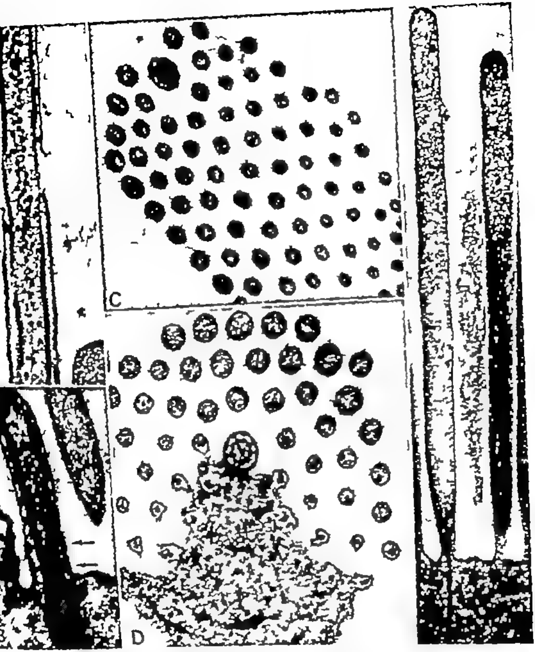

Fig. 17. Different views of kino- and stereocilia from macula utriculi and sacculi. In A and B granules are seen in the center of the kinocilium. In A arrows indicate macromolecular strands often seen in the fixed specimens. In B the arrows indicate the neck portion. C shows the most common arrangement with an excentrically positioned kinocilium, while D has a central kinocilium. In E some stereocilia are sectioned lengthwise. (A) × 32 500; (B) × 44 000; (C) × 30 000; (D) × 4_ 000; (E) × 11 000.

Figs. 28 32 The Nerve endings at type I and type II cells are of afferent (*Ne* 1) and efferent (*Ne* 2) nature Around the type I cell in Fig. 28 a nerve chalice (NC) is seen The membranes between the sensory cell and the nerve chalice form a regular double line (as seen in Figs. 8 and 29 A C and D) The distance between the two lines has been found (in several measured cells) to vary between 213 1 ± 37.3 Å and 93 1 ± 9 6 Å At certain levels, usually at the lower end of the type I cell (Fig. 28 white arrow) invaginations may be seen and these may be rather deep as in Fig. 30 C. In close relation to such invaginations, where the distance sometimes becomes minimal synaptic bars (Fig 8 B) or synaptic bodies or balls (in Figs 8 29 A B, C and D Fig. 30 A) may be seen These synaptic structures may become very irregular as in 29 D Synaptic bodies or bars are almost always found at afferent synapses but occasionally in serially sectioned specimens we have seen synaptic bodies in relation to richly granulated endings, regarded as of efferent nature (Fig. 9 E) Synaptic bars are found at both type I cells and at type II cells. In the squirrel monkey we have observed synaptic bars with a length of more than 5 μ They are surrounded by synaptic vesicles of the clear type Dense cored vesicles have never been observed by us in the sensory cells.

At many afferent endings at the type II cells irregular infoldings of the plasma membrane of the sensory cells can be seen (Fig. 30 A arrow at *Ne* 1 *a* Fig 31 A arrows)

At the efferent endings (*Ne* 2) there is often found a subsynaptic cistern (Fig 30 D arrow at *Ne* 2, Fig. 31 B arrow Fig. 3 B arrow) Ribosomes are often seen in relation to the inner membrane of this cistern Only occasionally are subsynaptic cisterns seen in relation to afferent endings (Fig. 30 D *Ne* 1) The efferent synapses contain large numbers of synaptic vesicles of the clear type with a diameter about 230 250 Å The afferent endings contain much fewer vesicles which are very variable in size They range from about 230 Å to more than 1 000 Å Both afferent and efferent endings contain a small number of dense cored vesicles (Fig. 29 B *Ne* 1) These can increase considerably in numb r for instance when the animals have received ototoxic antibiotics.

Fig. 28. Nerve chalice (*NC*) from maculi utriculi, with synaptic invagination (*A*), synaptic bar (*B*) and synaptic body (*C*). In the adjacent supporting cell multivesiculated body (*MVB*). × 27 000

Figs. 28–32 The Nerve endings at type I and type II cells are of afferent (Ne 1) and efferent (Ne 2) nature. Around the type I cell in Fig. 28 a nerve chalice (NC) is seen. The membranes between the sensory cell and the nerve chalice form a regular double line (as seen in Figs. 28 and 29 A, C and D). The distance between the two lines has been found (in several *measured cells) to vary between 213.1±37.3 Å and 293.1±29.6 Å. At certain levels,* usually at the lower end of the type I cell (Fig. 28 white arrow) invaginations may be seen and these may be rather deep as in Fig. 30 C. In close relation to such invaginations, where the distance sometimes becomes minimal, synaptic bars (Fig. 28 B) or synaptic bodies or balls (in Figs. 28, 29 A, B, C and D, Fig. 30 A) may be seen. These synaptic structures may become very irregular as in 29 D. Synaptic bodies or bars are almost always found at afferent synapses but occasionally in serially sectioned specimens we have seen synaptic bodies in relation to richly granulated endings, regarded as of efferent nature (Fig. 29 E). Synaptic bars are found at both type I cells and at type II cells. In the squirrel monkey we have observed synaptic bars with a length of more than 5 μ. They are surrounded by synaptic vesicles of the clear type. Dense cored vesicles have never been observed by us in the sensory cells.

At many afferent endings at the type II cells irregular infoldings of the plasma membrane of the sensory cells can be seen (Fig. 30 A, arrow at *Ne 1 a*, Fig. 31 A, arrows).

At the efferent endings (Ne 2) there is often found a subsynaptic cistern (Fig. 30 D, arrow at *Ne 2*, Fig. 31 B, arrow, Fig. 32 B, arrow). Ribosomes are often seen in relation to the inner membrane of this cistern. Only occasionally are subsynaptic cisterns seen in relation to afferent endings (Fig. 30 D, *Ne* 1). The efferent synapses contain large numbers of synaptic vesicles of the clear type with a diameter about 230–250 Å. The afferent endings contain much fewer vesicles which are very variable in size. They range from about 230 Å to more than 1 000 Å. Both afferent and efferent endings contain a small number of dense cored vesicles (Fig. 29 B, Ne 1). These can increase considerably in number for instance when the animals have received ototoxic antibiotics.

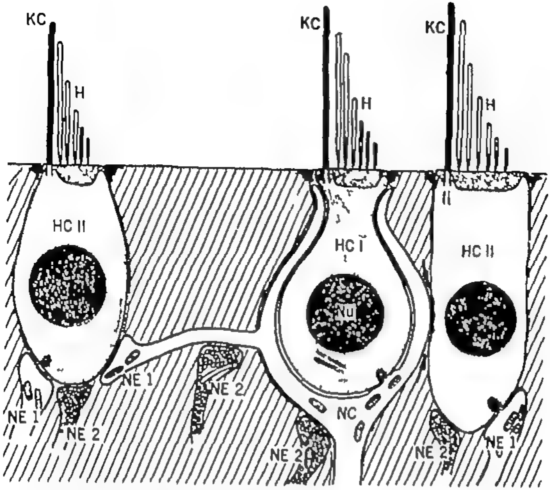

Fig 33 Schematic drawing of atypical, but not too uncommon innervation in the macular epithelia. The nerve chalice may form synaptic contact not only with a type I cell but also with a type II cell Occasionally extensions from a nerve chalice may reach and form synaptic contact with a type II cell The position of the efferent endings may also vary considerably but the principles given in the schematic drawing in Fig 3 represent the most common forms of innervation.

Fig 34 In A and B the lower portion of type I cells is seen and the arrows indicate regions where the double membrane between the nerve chal ce and the sensory cell has a peculiar appearance This is in the region of synaptic contact where the membrane has disappeared and granular structures are found instead of the membrane At first we regarded these formations as preparational artefacts but we have now observed the same kind of structures in many specimens from different animals and d fferent species The fixation in these cases has been good and many nearby sensory cells show the regular appearance of the membrane as in Figs 3 10 and 8 It is ery d fficult to understand the meaning of this disruption of the synaptic region We ha e stud ed thousand of cells and a tendency to a smaller scale disruption has been observed n ma y specimens The extensive disintegrat on or rearrangement seen in these micrograph has nly been found in the squirrel monky It is interesting to note that synaptic bars n monkeys are ften very long and may extend 5 μ in length (A) 9 000 (B) 40 .00

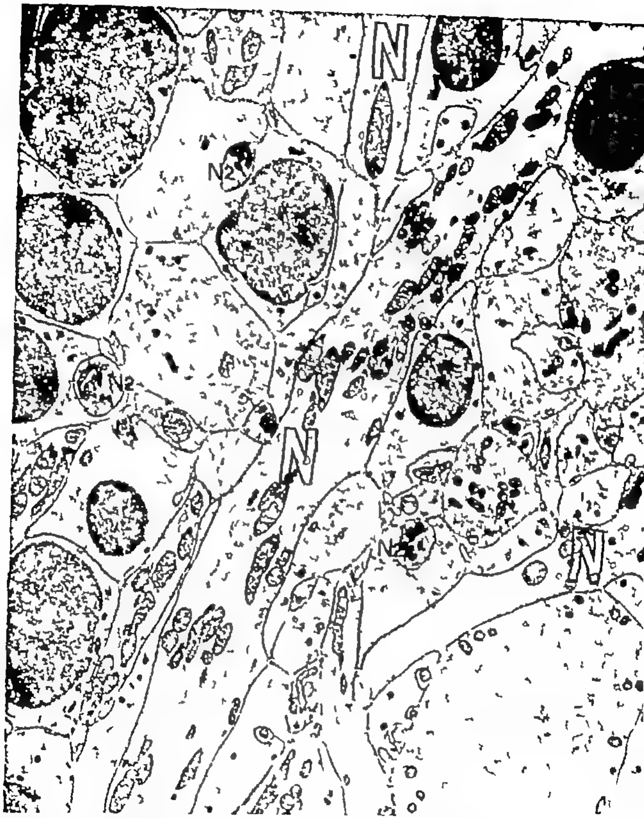

Fig. 35

Figs. 35 and 36. These two micrographs represent sections through macula sacculi parallel to the surface about 5 μ above the basement membrane. At this level many afferent nerve fibers (*N*) run almost horizontally before they turn upwards to the sensory cell. It is common to see branching nerve fibers. The granulated or efferent fibers (N_2) are very distinct from the afferent ones. They have much smaller and denser mitochondria and stand out very clearly. In Fig. 36 the appearance of the large mitochondria in the afferent fibers is well shown. All nuclei belong to supporting cells. Fig. 35 × 7 [illegible]00. Fig. 36 × [illegible]0 000.

Fig.

Fig. 37. Myelinated nerve (*MN*) below the basement membrane continuing inside the epithelium of macula utriculi. In this case the nerve sheds its myelin just at the basement membrane. More commonly the myelin ends some distance from the membrane and only infrequently is myelin seen in the epithelial layer. The supporting cells form a distinct layer with their nuclei close to the basement membrane. × 5 700

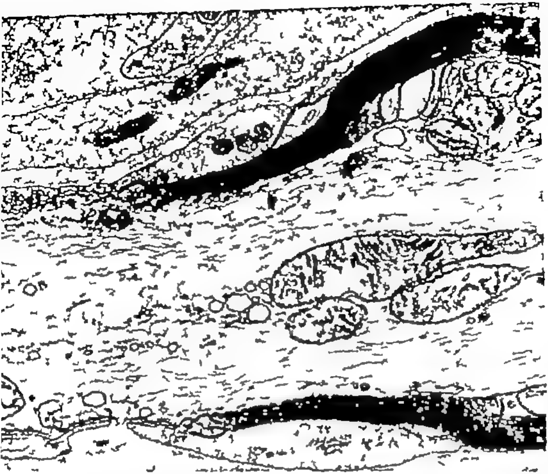

Fig 38.

Figs 38 and 39. Myelinated nerves shed their myelin below the macular epithelium, as seen in Figs 37. In Figs 38 and 39 details are seen of how the myelin unrolls from the axon. The regular layers of myelin form complicated folds and Schwann cell cytoplasm appears within the folds. These formations may be found in large numbers below the macula as described by Engstrom & Wersall (1958). Fig. 38 28 000, Fig. 39 (A) 68 000 (B) 73 500

High value	293.1±29.6 Å

Distance between sensory cell and nerve ending (synaptic region), type II cell

Afferent	123.0±27.8 Å
Efferent	161.0±18.5 Å

be a little wider in the nuclear region. As can be seen in Fig. 3 they are also provided with stereocilia and one kinocilium. These extend from a cuticle, which is often diffuse and which seems thinner and less dense than the cuticle of type I cells. It seems as though the stereocilia of type I cells spread out more than those of type II cells (Fig. 4).

The infracuticular region and the supranuclear region of type II cells seem to form a more uniform structure than is true for type I cells. There are several mitochondria below the cuticle, but they are distributed into the supranuclear area more than is the case with type I cells. The cytoplasm of these two regions contains more electron dense material, a slightly denser endoplasmic reticulum and more diffusely distributed Golgi complexes. Part of the difference in the type I and type II cells is the difference in distance between surface and nucleus. The infranuclear cytoplasm is similar in the two types of cells. In the long, type II cells the distance from surface to nucleus is often two or three times as large as in type I cells.

The major difference between type I and type II cells otherwise is in their relations to nerve terminals. While the type I cells are almost enclosed in a nerve chalice, the type II cells are innervated by boutons (synaptosomes) or fingerlike endings contacting the plasma membrane in several regions, but mainly in the infranuclear area, however synaptic contact regions are also found in the supranuclear region (Fig. 12).

The innervation of type I cells is by means of the nerve chalices earlier described. These endings have a very wide area of contact with the sensory cells and this contact differs in structure in different regions. From just below the cuticle, down to the nuclear level, there is a slightly irregular distance between the plasma membrane of the sensory cell and that of the nerve ending. The distance is about 175 Å, but below the nuclear level, it becomes larger and the membranes more regular. The membranes are parallel (Figs. 9, 10, 28) over large distances, and, in certain regions, distinct synaptic areas can be seen. In Figs. 28, 29 and 30 several different synaptic areas can be seen. The intercellular distance has been measured in many places along several cells and it has been found to vary between 213.1±37.3 μ and 293.1±29.6 μ. These measurements can be found in Table II on page 121. In the synaptic regions the distance between the cell membranes is considerably shorter. In some areas invaginations can be seen. The distance can become almost nil in certain areas

Fibrillar structures with a diameter of approximately 230 A arise close to the cuticle and the basal body of the kinocilium. The fibrils can be followed through the infracuticular supranuclear perinuclear and infranuclear regions to the vicinity of the nerve endings.

The supranuclear region (Figs. 7 8) contains a well developed endoplasmic reticulum with Golgi complexes, multivesciculated bodies, occasional lysosomes and filamentous structures of the type described earlier

The nucleus is round or ovoid and has a diameter of approximately 6 μ It has a finely granulated chromatine network and a nuclear membrane with many nuclear pores. The nucleolus is seldom prominent Laterally of the nucleus the cellular cytoplasm contains a few mitochondria (diameter approximately 0.5 μ length 2–3 μ)

The infranuclear region (6–7 μ) is the smooth round region below the nucleus. It contains a finely granular cytoplasm with groups of ovoid mitochondria poly ribosomes and a few granulated membranes with ribosomes (Figs. 9 10) At the lower end and along the sides of the infranuclear portion several specialized synaptic regions can be seen.

Almost the whole sensory cell of type I is enclosed in a nerve-chalice which will be described in relation to the innervation of the maculae The synaptic regions will be discussed in relation to this portion of our paper

The sensory cell of type II may vary considerably in length Some cells are quite short only 10–12 μ while others may reach from the surface almost down to the basement membrane In Fig. 4 is seen a type II cell with a length of more than 45 μ The type I cell with a length of 26 μ and another of 33 μ can be seen on either side of it A nearby type II cell is approximately 45 μ long The cells may vary in form also It seems as if the bulging of adjacent type I cells and their nerve chalices push the type II cells downwards and less often upwards Many of the type II cells have a cylindrical form or may

has not shown a corresponding staining either (Iurato et al. 1970). The further structure of the calyces will be shown in relation to Figs. 9 and 10.

The innervation of type II cells differs completely from that of type I cells. The type I cells contact only a single afferent nerve ending, while each type II cell contacts several afferent and efferent endings (Figs. 12, 31 A, B and 32 B).

The afferent endings are only sparsely granulated, hence, they appear to have little density in the electron micrograph. They form synaptic contacts with the sensory cells, and several types of synpatic structures can be seen on the side of the sensory cell. They are provided with large mitochondria (0.5–0.9 μ) (Figs. 30 A, 31 A). They contain a few vesicles with varying diameters often amounting to 600–800 Å. On the sensory cell side there are synaptic bars, bodies or balls. We have never seen the very long bars observed in type I cells of the squirrel monkey. The bars are usually only 0.3–0.5 μ in length. They often arise at a dense synaptic region at the area of contact between nerve ending and sensory cell. There is often a coated invagination in the neighborhood as well. All intermediate stages can be seen between bars, bodies and balls, and the synaptic formations also have uniformly sized vesicles on the side of the sensory cell. The vesicles have a diameter of about 230 Å, measured on many vesicles in both utricle and saccule. An exact measurement is difficult as the vesicles are often slightly irregular and not all are cut in the middle. The synaptic bodies usually have a diameter of about 0.2–0.3 μ.

The efferent endings are richly granulated (Figs. 30 D, 31 B). They have smaller mitochondria, of a diameter of 0.15–0.20 μ, and they have a different contact with the sensory cells. Generally they are filled with synaptic vesicles, of a diameter of about 230 Å. It is possible that some efferent fibers form contacts with afferent fibers also. Close to the synaptic membrane there are no mitochondria but this portion of the efferent ending is full of synaptic vesicles. A kind of presynaptic grid close to the synapse can often be seen (cf. Engstrom & Ades, 1972). Inside the plasma membrane of the sensory cell there is often a subsynaptic cistern (Fig. 31 B). Such cisterns are particularly well developed in the cochlear hair cells and are a common but not constant finding in these type II cells. The efferent endings of type I cells are usually found close to the stem of the nerve calyx. The efferent endings of type II cells are found at several levels from the nucleus downwards. It is extremely difficult to follow in detail the course of the efferent nerve fibres inside the macular epithelia. They run a complicated and richly branching course in the lower part of the sensory epithelium and there is good evidence of "en passant" synapses between efferent nerve fibres both with sensory cells and with afferent fibres.

In the squirrel monkey the nerve fibres inside the macular epithelia are unmyelinated and the myelin sheaths begin directly below the basement membrane, as can be seen in Figs. 37–40. Only very occasionally can myelin be found (in infoldings) above the basement membrane. In certain fishes myelinated fibres are regularly found in the macular sensory epithelium. The process of

(cf Engström et al 1965) and there is a question whether there is not real fusion of membranes sometimes. Often times the infoldings have no increased density In other cases, they become much darker than the rest of the membrane and not infrequently an infolding becomes a coated invagination possibly developing into a coated vesicle or vesicles (Figs. 30 A B and 31 A) In other regions dense synaptic areas are attached to a synaptic bar or body (Figs. 29 A B C and D) The length of the synaptic bar varies in different animals, some of them being more than 5 μ long Some bars seem to fold or break others have irregular processes ending in condensed dark synaptic formations (Fig 29 D) Flock (personal communication) has seen a beginning synaptic body or ball formation in the side line organ of embryological material and has seen that this bar formation begins near the nucleus. We have no comparable information from our adult monkeys but we have always found synaptic bars and bodies to have close contact with the dense synaptic areas. The synaptic bars, bodies or balls are regularly found at afferent nerve endings however we have seen in a few cases, in serially sectioned material synaptic bodies contacting efferent endings also (Fig 29 E) Vesicles can often be seen inside afferent endings which are usually larger than those in efferent endings. Some dense cored vesicles, usually large ones, can be seen both in afferent and efferent endings. We have not seen dense cored vesicles inside sensory cells. Engström et al (1972) have reported extensive accumulations of dense cored vesicles in the inner spiral bundle of the organ of Corti but we have never observed any comparable accumulations in or beneath the maculae The thickness of the nerve chalices around type I cells diminishes at the nuclear level often to about 0 4 μ The nerve chalice widens toward the stem and the stems may be of different thicknesses. The cytoplasm of the chalice contains mitochondria which are considerably larger than those found in efferent endings. Their diameter is between 0 5–1 μ while those of the efferent endings on the outside of the chalices have a diameter of only 0 15–0 20 μ The efferent mitochondria are also much denser than those found in the chalices. The afferent fibers contain many nerve tubuli and filaments (Figs. 35 and 36) which can be followed high up in the chalices. Smith (1956) reported on vesicles in the uppermost portion of the calyces and this has been verified in the present study She appreciated that these vesicles were of synaptic nature and they have a distinct resemblance to synaptic vesicles. The interesting thing is that if vesicles are of synaptic nature they are usually found on the presynaptic side and the nerve chalice is post synaptic. The synaptic organization at the lower end of the type I cell (Figs 28 29 A and 29 C) is distinctly along the line that the sensory cell contains pre synaptic vesicles around synaptic bars bodies or balls, and the chalice represents the postsynaptic side The nature of the vesicles at the upper margin of the chalices is therefore intriguing but their function is obscure It is interesting to see that in Maillet stained specimens the efferent granulated endings at the base of the chalices stain darkly but we have never found that the rims of the chalices take up the color in a similar way Acetylcholine esterase staining

ZUSAMMENFASSUNG

In der Arbeit wird eine Übersicht über die Struktur der Sinnesepithelien in der Macula sacculi und Macula utriculi von Saimiri Sciureus (squirrel monkey) gegeben.

Die Verfasser haben eine systematische Untersuchung von der Form und Ultra struktur der Sinneszellen und ihren Stützzellen gemacht und beschreiben auch genau die Innervation der Sinneszellen von sowohl Typus I als auch Typus II (nach Wersäll).

Die Arbeit wird von einer grossen Anzahl Mikrophotographien begleitet und besonderen Wert wurde auf bildliche Präsentation der Sinnesepithelien gelegt.

myelinization and the complicated *infoldings* have been described by Engström & Wersäll (1958) Similar findings have also been found regularly in the squirrel monkey

The supporting cells in the maculae reach from the basement membrane to the surface of the epithelium They have a very irregular form and their nuclei are almost always found just above the basement membrane and below the sensory cells. The irregular form of the supporting cells is caused by their location between the sensory cells. At the surface they separate the individual sensory cells which are usually surrounded by a "ring" of supporting cells. This has been beautifully demonstrated by Lindeman (1969) and by Watanuki (1972) The nuclei of the cells are ovoid with the chromatin frequently lying in clusters centrally but also at the periphery The cytoplasm contains many cytoplasmic organelles as can be seen in many of the micrographs. There are often well developed Golgi complexes, many mitochondria and occasional lipid droplets. The upper part of the supporting cell contains large numbers of round or ovoid granules often with ribosomes along their surface. The nature of these granules is not yet clear

The surface of the supporting cells is covered with a moderate number of microvilli of a varying length sometimes almost 1 μ long These microvilli seem to be attached in some way to the gelatinous matter found above the surface The surface portion of the supporting cells contains a dense material which takes part in the formation of the reticular membrane This membrane has a very typical appearance (Lindeman 1969 Watanuki 1971 1972) The individual bars are very irregular as can be seen in many of our micrographs.

It has been repeatedly described in older literature that the supporting cells contain supporting filaments but this could not be well documented by electron microscopy In the present study it has regularly been observed that the supporting cells contain very thin fibrillar structures forming a reinforcing structure within the cells. These fibrils reach from the base of the cells close to the surface where they seem to integrate with the thin filament found in the desmosomes (Figs. 9 and 10)

SUMMARY

This study provides a description of the sensory epithelium of the maculae utriculi and sacculi in the squirrel monkey Particular interest has been devoted to a description of the ultrastructure of the maculae.

The study contains a large number of transmission electron micrographs and also some scanning electron micrographs and schematic drawings. Special attention has been given to the innervation of the sensory cells The sensory cells are of two distinct types named types I and II according to Wersäll Their structure and innervation is very different and many of these details can be seen in the micrographs A series of micrographs demonstrate the myelinization region of the afferent nerve fibres.

Abstract

This supplement presents audiological, vestibular and neurological data collected from 61 persons with multiple sclerosis. These persons were administered an extensive battery of tests in each of the aforementioned areas in an effort to learn more about the function of the human central auditory and vestibular nervous systems. Auditory and vestibular findings were analyzed in relation to neurological involvements of the low brainstem, high brainstem, midbrain and cortical levels as inferred from the neurological examination. Attention was also given to the implications to be drawn from the test results in light of the fact that multiple sclerosis is a disease of the central nervous system.

The neurological evaluation consisted of history taking, examination of clinical laboratory and medical reports (available for all patients), and a thorough clinical neurological examination by the project's neurologist. From such procedures and other special procedures when needed, sites of lesions were inferred by the project neurologist in terms of four general levels of the central nervous system. These inferred levels of damage were considered during analysis of the auditory and vestibular data.

The auditory test battery consisted of routine pure tone and speech threshold testing, the establishment of discrimination ability for monosyllables, and of a series of special tonal and speech tests. The 6 special tonal tests included tests of adaptation, loudness function, and short increment sensitivity as well as 3 tests of binaural auditory function.

The 4 speech tests included discrimination of words in the presence of ipsilateral white noise, versus a contralateral competing speech message, in various filtered modes, and in various binaural masking situations.

The vestibular evaluation employed 4 main procedures, namely a group of tests concerned with visually induced eye movements, a check for spontaneous nystagmus, a search for positional nystagmus, and a look at response to caloric stimulation. All of the evaluation was conducted utilizing electronystagmographic techniques.

The results were considered individually and in terms of incidence of patterns of results. Generally neurological evaluation of the 61 subjects revealed symptoms suggesting multi-leveled lesions of the central nervous system, particularly in the midbrain and brainstem. Auditory evaluations demonstrated a marked diversity of auditory aberrations which were most commonly elicited by tests requiring response to a sustained stimulus, by tests requiring discrimination of speech in conditions other than quiet, and by binaural masking tests. Vestibular evaluations showed a similar variety of noteworthy results. Abnormal visually induced eye movements, positional nystagmus, and hyper excitability in response to caloric stimulation were the most common findings.

Abstract

This supplement presents audiological, vestibular and neurological data collected from 61 persons with multiple sclerosis. These persons were administered an extensive battery of tests in each of the aforementioned areas in an effort to learn more about the function of the human central auditory and vestibular nervous systems. Auditory and vestibular findings were analyzed in relation to neurological involvements of the low brainstem, high brainstem, midbrain and cortical levels as inferred from the neurological examination. Attention was also given to the implications to be drawn from the test results in light of the fact that multiple sclerosis is a disease of the central nervous system.

The neurological evaluation consisted of history taking, examination of clinical, laboratory and medical reports (available for all patients), and a thorough clinical neurological examination by the project's neurologist. From such procedures and other special procedures when needed, sites of lesions were inferred by the project neurologist in terms of four general levels of the central nervous system. These inferred levels of damage were considered during analysis of the auditory and vestibular data.

The auditory test battery consisted of routine pure tone and speech threshold testing, the establishment of discrimination ability for monosyllables, and of a series of special tonal and speech tests. The 6 special tonal tests included tests of adaptation, loudness function, and short increment sensitivity as well as 3 tests of binaural auditory function.

The 4 speech tests included discrimination of words in the presence of ipsilateral white noise, versus a contralateral competing speech message, in various filtered modes, and in various binaural masking situations.

The vestibular evaluation employed 4 main procedures, namely a group of tests concerned with visually induced eye movements, a check for spontaneous nystagmus, a search for positional nystagmus, and a look at response to caloric stimulation. All of the evaluation was conducted utilizing electronystagmographic techniques.

The results were considered individually and in terms of incidence of patterns of results. Generally neurological evaluation of the 61 subjects revealed symptoms suggesting multi-leveled lesions of the central nervous system, particularly in the midbrain and brainstem. Auditory evaluations demonstrated a marked diversity of auditory aberrations which were most commonly elicited by tests requiring response to a sustained stimulus, by tests requiring discrimination of speech in conditions other than quiet, and by binaural masking tests. Vestibular evaluations showed a similar variety of noteworthy results. Abnormal visually induced eye movements, positional nystagmus, and hyperexcitability in response to caloric stimulation were the most common findings.

1 Background to the Study

I. INTRODUCTION

A review of the literature reveals a diversity of auditory behavior associated with multiple sclerosis. This diversity is not unexpected when one recalls that multiple sclerosis is a fluctuating, albeit basically progressive disease of the central nervous system wherein the site(s) of the lesion(s) varies from one patient to the next.

Given this variability the study of auditory dysfunction due to multiple sclerosis in conjunction with neurological evaluations can increase one's insight into normal and abnormal auditory function in two ways. First, administration of a battery of special auditory tests can provide additional information about how multiple sclerosis patients perform on these tests and the types of disruption of normal auditory function to be expected. Second, correlation of auditory test results with the clinically inferred sites of lesion which are provided by competent neurologists can help increase one's understanding of the relationship between lesions of the central nervous system and breakdowns in hearing ability.

The present paper reviews the auditory aberrations of a fairly large group of patients with multiple sclerosis. The paper also analyzes the relation between these aberrations and neurological signs exhibited by these patients. Vestibular findings on some of the patients are also reported. Before embarking upon these discussions, however, a brief review of some key aspects of multiple sclerosis is pertinent.

II. NATURE OF MULTIPLE SCLEROSIS

Multiple sclerosis is one of the most common degenerative diseases of the central nervous system found throughout the temperate zone. It is characterized clinically by remissions and relapses occurring over a period of months-to-years, with the signs and symptoms reflecting patchy involvement of the neural axis. Although the disease is pleomorphic in its presentation, its pathologic lesions, referred to as "plaques" are confined to the white matter of the brain, brainstem, and spinal cord. The cerebral lesions are frequently seen in the paraventricular areas, especially in relation to the lateral ventricles. In the brainstem, the lesions are often present around the third and fourth ventricle. In the spinal cord, the lesions are confined to the white matter and do not extend beyond the root entry zone. Another area of predilection is the optic nerve. It has been estimated that about 40% of patients with multiple sclerosis suffer from optic neuritis. The most common brainstem and midbrain signs include incoordination, nystagmus, diplopia and/or the medial longitudinal fasciculus (MLF) syndrome.

The histopathological characteristics of the plaques are quite typical, and the loss of myelin with preservation of the axon is fundamental to the lesion. In addition, the younger lesions demonstrate mono-nuclear infiltration, oligodendroglial degeneration, and microglial reaction. The older lesions show fibrous astrocytic reaction. Perivascular reaction and edema are also quite characteristic of the lesions. During active phases of the disease, cerebrospinal fluid shows pleocytosis, normal or elevated total protein, and a significant rise in gamma globulin fraction.

III. VESTIBULAR INVOLVEMENT

It has long been well recognized that patients with multiple sclerosis may report vertigo or

dizziness as one of their complaints, sometimes, although rarely as the presenting symptom Multiple sclerosis patients often exhibit nystagmus, with a reported incidence of 5 to 57 (Leidler 1917 Mygind, 1933 von Leden & Horton 1948 Bentzen et al. 1951 Hallberg, 1956 Cannizzaro 1957 Salonna & Carbonara 1959 Parker et al 1962 Citron et al 1963 Preibish-Effenberger 1963 Rose & Daly 1964 Dayal et al. 1966 Rataj & Mizake 1966 Collard et al., 1969) Dissociated and ataxic nystagmus have been commonly found in multiple sclerosis patients (e.g., von Leden & Horton, 1948 Parker et al 1962) and was thought pathognomonic of multiple sclerosis by Harris (1944) Spontaneous and/or lateral gaze nystagmus were exhibited by patients with multiple sclerosis reported by Hallberg (1956) Citron et al (1963) Dayal et al (1966) and Collard et al (1969) These varieties of nystagmus as well as the dizziness and unsteadiness often described by multiple sclerosis patients are probably due to foci of demyelination which may occur anywhere from the cerebellum and root of the VIIIth nerve up through the remainder of the central vestibular system (Leidler 1917 Ward et al 1965)

IV AUDITORY INVOLVEMENT

Auditory symptomatology though recognized is not completely understood and there appears to be no agreement in the literature as to the nature of hearing loss in multiple sclerosis Leidler (1917) described his findings in 13 patients with multiple sclerosis who came to autopsy All had nystagmus and he particularly searched for damage within the vestibular system His examination extended from the end organ to the ocular nuclei and included the cerebellum he found much of this area susceptible to disruption by multiple sclerosis The plaques ranged in size from flecks within bundles of ascending fibers to massive lesions that had largely demyelinated the brainstem. Findings in the auditory system were similarly diverse Lesions were noted to involve the VIIIth nerve the cochlear nuclei the trapezoid complex, and the higher nuclear centers and pathways. In one case for example, a large plaque occupied a portion of the pons and medulla The acoustic nerve was attacked on one side at its insertion to the pons and was mostly encompassed by the plaque throughout the pons and medulla. The lateral lemniscus, however was free of demyelination On the other side sclerotic foci were confined to the region of the vestibular nuclei and the floor of the fourth ventricle

Brock & Gagel (1933) reported the case of a 25 year old male who died two months after the onset of what proved to be acute multiple sclerosis At the time of death the patient had a bilaterally severe hearing loss (by forks and subjectively) which had paralleled in severity the progression of the disease process. Autopsy revealed a large plaque in the area of the right ventral cochlear nucleus near the VIIIth nerve entrance. Other plaques were found bilaterally in the medulla at the level of the superior olives which affected the vagal and glossopharyngeal nuclei The absence of glial cells suggested a recent disease process.

Dix (1968) described a 70 year old male who died three months after onset of an episode much like the one reported by Brock & Gagel Included in the symptomatology were ataxia, slurred speech slight nystagmus in both directions, and clumsiness of the right arm and leg Palsies of cranial nerves III–XII and signs of cerebellar damage were present on the right side Despite the widespread cranial nerve signs vestibular abnormalities appeared slight

Auditory tests revealed a severe hearing loss in the right ear characterized by a drop-off to no hearing by 4 000 Hz The left ear had only a slight high frequency loss Fowler's alternate binaural loudness balance test demonstrated an absence of recruitment at 1 000 Hz and decruitment at 500 and 2 000 Hz. Discomfort levels for pure tones were sought and the findings, according to Dix confirmed the lack of recruitment in the right ear

At post mortem examination sectioning of the brainstem revealed a grey plaque which Dix

judged as probably being due to multiple sclerosis. The plaque occupied an area near the right inferior cerebellar peduncle. At the level of the insertion of the VIIIth auditory nerve to the brainstem, the plaque encompassed a large area including the dorsal and ventral cochlear nuclei, the trapezoid body and the VIIIth nerve fibres near the cochlear nuclei. Overall, nearly two-thirds of the right half of the brainstem was damaged at this level. The estibular nuclei however were largely spared. These histological findings are of particular interest in view of the hearing impairment in this case.

Many different suggestions about type and site of lesion have been offered to explain the auditory aberrations present in some cases of multiple sclerosis. Such diversity probably is attributable to the episodic nature of the disease and to the various test procedures used by investigators in evaluating the auditory function of patients with multiple sclerosis. Mygind (1933) concluded that since multiple sclerotic patients usually had bass deafness, the cause of such deafness must be a choked labyrinth" rather than "neuritis or nuclear damage. He did acknowledge, however that auditory behavior in some persons with multiple sclerosis mimicked that of cases with VIIIth nerve tumor. Hallpike (1967) claimed that the lesions of multiple sclerosis are confined to the central nervous system. They may occur in the cranial nerves, but are then restricted to the zone of the so-called glial protrusion which is correctly regarded as an extension of the central nervous system (p. 493).

Fisch (1970) pointed out that the VIIIth nerve has two distinct segments which differ histologically. The central part has the histological character of fiber tracts within the brain substance (that is, the endoneurium and the neurilemmal sheath are missing and the supporting tissue consists of glial cells). The peripheral part has the appearance of a peripheral nerve (p. 107). He also stated that " the *glial* portion of the auditory nerve which traverses the subarachnoid space, is more vulnerable to injury by toxic or infectious influences than the peripheral portion and is also more vulnerable when compared to other cranial nerves" (p. 102).

Multiple sclerosis is known to affect nervous tissue supported by glial cells, such that one would logically expect to find multiple sclerosis plaques involving the glial portion of the VIIIth nerve. Skinner (1929) stated that the point of junction of the peripheral and central parts of the auditory nerve varies in its distance from the middle cerebellar peduncle from 10 to 13 mm in the human male and from 7 to 10 mm in the female. This junction is frequently more distal in the " vestibular than in the cochlear nerve (and) is in most instances within the porus acousticus" (Nager 1969 p. 252).

Citron et al. (1963) specifically assigned the auditory damage in multiple sclerosis to the VIIIth nerve between the spiral ganglia and the insertion of the nerve trunk into the cochlear nucleus. Similar placement of damage was inferred by Hennebert (1966) and by Rose & Daly (1964) on the basis of marked tone decay and on the demonstrable reversibility of such decay and of the pure tone loss. They suggested that the remissive nature of the symptoms was attributable to either a *reversible* demyelination or a perimyelinic edema, i.e. an edemic pressure on the nerve which occurred only during active stages of the disease. Sakamoto & Ichiro (1968) reported excessive adaptation from 2 multiple sclerotic patients during Bekesy audiometry thus indicating the possibility of VIIIth nerve lesion. Antonelli & DeMitri (1963) suggested that when hearing loss is demonstrable for pure tones, the lesion involves the VIIIth nerve or cochlear nucleus. Further they stated, in cases whose only auditory dysfunction is restricted to special speech tests, the damage probably lies at higher regions of the central auditory system. Parker et al. (1962) speculated that hearing impairment due to multiple sclerosis results from damage to "second order neurons". Damage at higher levels, especially within the pons and midbrain, was suggested by Rataj & Miszke (1966) and by Kehajov (1965 1967).

Ward Cannon & Lindsay (1965), after con-

sidering much of the speculation just cited concluded that "The loci of the lesions responsible for auditory vestibular and cranial nerve signs and symptoms have generally been attributed to lesions encroaching on the brainstem nuclei and their suprasegmental or intersegmental pathways rather than the peripheral nerves Several reports contained authenticated cases of true involvement of the nerve roots by plaque-like lesions. Close scrutiny (of this evidence) suggested that the lesions were direct extensions of dorsal lateral brainstem plaques that did not extend into the peripheral nerve proper (p 1035) After review of the pertinent literature, including Leidler's (1917) autopsy population Ward et al concluded "In our review no well documented evidence of multiple sclerosis involving peripheral or cranial nerves, beyond the region where the nerve trunk enters the central nervous system, was found" (p 1035)

There is no agreement in the literature regarding the incidence and types of hearing impairment associated with multiple sclerosis Many reports of hearing loss for pure tones have appeared (Dundas-Grant, 1921–22 von Leden & Horton 1948 Bentzen et al., 1951 Salonna & Carbonara 1959 Simpkins, 1961 Antonelli & DeMitri 1963 Preibish Effenberger 1963 Ivers & Goldstein 1963 Rose & Daly 1964 Kehajov 1965 Ravenna, 1965 Dayal et al 1966 LeZak & Selhub 1966 Dayal & Swisher 1967 Kehajov 1967 Shulga 1967 Taniewski & Kugler 1967 Parker et al 1968 Sakamoto & Ichiro 1968 Williams 1968 Conraux & Collard 1969 and Dayal et al 1970) The studies mentioned above described population sizes from 2 364 multiple sclerotic patients and incidences of pure tone loss from 1–86 % Most commonly however incidence of hearing loss was about 50 Almost every possible audiometric configuration was noted but mild high frequency losses were most common Collard et al (1969) claimed that the mild nature of the pure tone loss was characteristic of multiple sclerosis. Highfrequency hearing loss was also most prevalent in case studies reported by Hallberg (1956) Cannizzaro (1957) Parker et al (1962) Citron et al (1963) and Rataj & Mizle (1966) Sopek & Sipowicz (1969) however described a transitory unilateral low frequency hearing loss in 1 case

Instances of poor speech discrimination in spite of normal pure tone sensitivity have also been observed in cases of multiple sclerosis (Antonelli & DeMitri 1963 Litton & McCabe 1967) A noteworthy example was reported by Citron et al (1963) The patient in question recovered over a period of three weeks to normal sensitivity for all tones from only a remnant of response at low frequencies The pure tone recovery was essentially complete during the second week but at this time speech discrimination in quiet was only 44 a week later it was 100 % Reger discussed a similar case in 1964 Bentzen et al (1951) noted that articulation functions for both monosyllabic and bisyllabic words were less steep than normal for 10 multiple sclerotic patients with normal audiograms In the same vein von Leden and Horton (1948) reported that many persons with no pure tone loss complained of subjective hearing problems Conversely Parker et al (1968) found good speech discrimination (80 or better) for 4 of 6 persons in spite of some high frequency hearing loss. Interestingly 1 patient with normal pure tone thresholds could understand no words at all

Persons with multiple sclerosis are sometimes susceptible to excess disruption of speech intelligibility when the listening task is made unusually difficult Nine of the patients seen by Dayal et al (1966) showed an inordinately decreased score when speech discrimination was tested at a signal/noise (S/N) ratio of + 10 dB Twenty two of the 50 patients reported by Preibish Effenberger (1963) experienced breakdown of performance on Matzker's distorted speech test Antonelli & DeMitri (1963) found 3 of their 13 cases to have abnormal difficulty with low redundancy speech items.

Dix (1965), using the Fowler test found lack of recruitment for the majority of 31 persons having multiple sclerosis and unilateral hearing loss. However a few showed partial or complete recruitment at 1 or more of the frequencies from

500–4 000 Hz. Hallberg (1956) reported a case where recruitment was absent, and 1 case described by Citron et al. (1963) showed decruitment. Kehajov (1967) observed partial or complete recruitment in some of his 50 cases, no recruitment in others, and decruitment in still others.

V SUMMARY

The foregoing review makes clear the fact that multiple sclerotic lesions vary from case to case and, in a single individual, from time to time. It also highlights the fact that multiple sclerosis disturbs auditory behavior in some instances and that the resulting symptomatology is diverse.

sidering much of the speculation just cited concluded that "The loci of the lesions responsible for auditory vestibular and cranial nerve signs and symptoms have generally been attributed to lesions encroaching on the brainstem nuclei and their suprasegmental or intersegmental pathways, rather than the peripheral nerves Several reports contained authenticated cases of true involvement of the nerve roots by plaque-like lesions. Close scrutiny (of this evidence) suggested that the lesions were direct extensions of dorsal lateral brainstem plaques that did not extend into the peripheral nerve proper" (p 1035) After review of the pertinent literature, including Leidler s (1917) autopsy population Ward et al. concluded "In our review no well documented evidence of multiple sclerosis involving peripheral or cranial nerves, beyond the region where the nerve trunk enters the central nervous system was found" (p 1035)

There is no agreement in the literature regarding the incidence and types of hearing impairment associated with multiple sclerosis Many reports of hearing loss for pure tones have appeared (Dundas-Grant 1921–22 von Leden & Horton 1948 Bentzen et al 1951 Salonna & Carbonara, 1959 Simpkins, 1961 Antonelli & DeMitri 1963 Preibish Effenberger 1963 Ivers & Goldstein 1963 Rose & Daly 1964 Kehajov 1965 Ravenna, 1965 Dayal et al., 1966 LeZak & Selhub 1966 Dayal & Swisher 1967 Kehajov 1967 Shulga 1967 Taniewski & Kugler 1967 Parker et al 1968 Sakamoto & Ichiro 1968 Williams, 1968 Conraux & Collard 1969 and Dayal et al 1970) The studies mentioned above described population sizes from 2 364 multiple sclerotic patients and incidences of pure tone loss from 1–86 Most commonly however incidence of hearing loss was about 50 Almost every possible audiometric configuration was noted, but mild high frequency losses were most common Collard et al (1969) claimed that the mild nature of the pure tone loss was characteristic of multiple sclerosis. Highfrequency hearing loss was also most prevalent in case studies reported by Hallberg (1956), Cannizzaro (1957) Parker et al (1962) Citron et al (1963), and Rataj & Mrazek (1966) Sopek & Sipowicz (1969) however described a transitory unilateral low frequency hearing loss in 1 case

Instances of poor speech discrimination in spite of normal pure tone sensitivity have also been observed in cases of multiple sclerosis (Antonelli & DeMitri 1963 Litton & McCabe 1967) A noteworthy example was reported by Citron et al. (1963) The patient in question recovered over a period of three weeks to normal sensitivity for all tones from only a remnant of response at low frequencies The pure tone recovery was essentially complete during the second week but at this time speech discrimination in quiet was only 44 a week later it was 100 . Reger discussed a similar case in 1964 Bentzen et al (1951) noted that articulation functions for both monosyllabic and bisyllabic words were less steep than normal for 10 multiple sclerotic patients with normal audiograms In the same vein von Leden and Horton (1948) reported that many persons with no pure tone loss complained of subjective hearing problems. Conversely Parker et al (1968) found good speech discrimination (80 or better) for 4 of 6 persons in spite of some high frequency hearing loss Interestingly 1 patient with normal pure tone thresholds could understand no words at all

Persons with multiple sclerosis are sometimes susceptible to excess disruption of speech intelligibility when the listening task is made unusually difficult Nine of the patients seen by Dayal et al (1966) showed an inordinately decreased score when speech discrimination was tested at a signal/noise (S/N) ratio of +10 dB Twenty two of the 50 patients reported by Preibish Effenberger (1963) experienced breakdown of performance on Matzker s distorted speech test Antonelli & DeMitri (1963) found 3 of their 13 cases to have abnormal difficulty with low redundancy speech items

Citron et al (1963) and Rataj & Miszke (1966) Sopek & Sipowicz (1969) however described a transitory unilateral, low frequency hearing loss in 1 case

Instances of poor speech discrimination in spite of normal pure tone sensitivity have also been observed in cases of multiple sclerosis (Antonelli & DeMitri 1963 Litton & McCabe 1967) A noteworthy example was reported by Citron et al (1963). The patient in question re covered over a period of three weeks to normal sensitivity for all tones from only a remnant of response at low frequencies. The pure tone re covery was essentially complete during the sec ond week but at this time speech discrimination in quiet was only 44 a week later it was 100 Reger discussed a similar case in 1964 Bentzen et al (1951) noted that articulation functions for both monosyllabic and bisyllabic words were less steep than normal for 10 multiple sclerotic patients with normal audiograms In the same vein von Leden and Horton (1948) reported that many persons with no pure tone loss complained of subjective hearing problems. Conversely Parker et al (1968) found good speech discrim ination (80% or better) for 4 of 6 persons in spite of some high frequency hearing loss. Interestingly 1 patient with normal pure tone thresholds could understand no words at all

Persons with multiple sclerosis are sometimes susceptible to excess disruption of speech intel ligibility when the listening task is made unusu ally difficult Nine of the patients seen by Dayal et al (1966) showed an inordinately decreased score when speech discrimination was tested at a signal/noise (S/N) ratio of + 10 dB Twenty two of the 50 patients reported by Preibish Effenberger (1963) experienced breakdown of performance on Matzker s distorted speech test Antonelli & DeMitri (1963) found 3 of their 13 cases to have abnormal difficulty with low redundancy speech items.

Dix (1965), using the Fowler test found lack of recruitment for the majority of 31 persons having multiple sclerosis and unilateral hearing loss. However a few showed partial or complete recruitment at 1 or more of the frequencies from

Research Laboratory (Medical School Branch). Whenever possible, all the tests reported below were administered, but special considerations in individual cases made it impossible always to do so. The number of times each test was given is reported in the results chapter. What follows in this section is a description of the several auditory tests and the rationale for including each one.

A. Pure tone audiometry

The evaluation started with conventional discrete frequency pure tone audiometry. This basic test provided data on subjects' hearing sensitivity across the frequency range from 125–8 000 Hz, on air-bone relationships in cases of loss in hearing sensitivity and on the configuration of impairment. Comparison of this configuration with the contours of loss generally associated with various auditory diseases allowed identification of instances where the auditory system had been coincidentally damaged by causes other than multiple sclerosis. In instances which exhibited such coincidental effects, the task was to estimate (from all the data at hand) the degree and configuration of hearing loss attributable to multiple sclerosis. One of the goals was to avoid assigning to multiple sclerosis any pure tone deficits which it had not produced. Fortunately, since multiple sclerosis strikes most often in the young adult years, complicating coincidental pathology was absent in most cases.

B. Speech audiometry

Traditional measures of speech reception threshold (for spondees) and intelligibility of monosyllabic words [NU 6 version presented at 40 dB re SRT (Tillman & Carhart, 1966)] were obtained. These and all other speech test materials were stored on magnetic tape. Later 4 other speech tests were administered. In the first 3 of these discrimination of monosyllables had to be made under more difficult listening conditions. In the fourth, spondees were the test items.

One test consisted of monosyllables (NU 6 version at 40 dB re SRT) presented monaurally and simultaneously with white noise. The S/N ratio was 0 dB. Dayal et al. (1966) found that 9 of 13 multiple sclerotic patients so tested experienced substantial breakdown in discrimination when they presented monosyllables in white noise at an S/N ratio of +10 dB. In our laboratory most normals score from 70 to 80 % correct on this test. It has been our clinical experience that some persons with peripheral (cochlear or VIIIth nerve) involvements experience substantial difficulty with this test even though their speech discrimination in quiet for the test materials is excellent (90–100 %). Discrimination of monosyllables in the presence of white noise also has been found to be substantially decreased in some patients with surgically confirmed temporal lobe lesions (Sinha, 1959).

A second test was designed to search for lesions at the brainstem level. It was a modification of the Matzker (1959) filtered speech test. NU6 monosyllables were recorded synchronously on 2 channels of a magnetic tape with pass-bands of 250–750 Hz on channel 1 and 1250–1750 Hz on channel 2. When normals were asked to integrate the 2 channels at a sensation level of +26 dB re SRT they scored about 80 % correct irrespective of whether both channels were presented to 1 ear or 1 was administered via the right ear and the other via the left ear or vice versa. Breakdown on this test is generally accepted as being a clue to involvement of the auditory system in the brainstem (Matzker, 1959). Pratt-Ellenberger (1963) gave a Matzker-type test to 50 subjects with multiple sclerosis and found that ... of them did not integrate the 2 channels normally.

The third special speech test employed competing messages. This test consisted of presentation of NU6 monosyllables at 50 dB SL to 1 ear while competing sentences were administered at 60 dB SL to the other ear. It is an easy listening task for most persons except for those with involvement of the auditory system at the cortical level. The usual score for normal hearers is between 90 and 100 %. In other words, a listener can keep the two trains of stimuli iso-

2 Investigative Plan

I INTRODUCTION

The heterogeneity of past findings regarding the auditory responses of multiple sclerosis patients is undoubtedly due partly to differences in the sites and extents of lesions produced by the disease and partly to the variety of hearing tests employed by past investigators This situation prompted the present study Its goal was to obtain auditory neurological, and vestibular data concurrently so that relations between breakdown in hearing function and inferred site of lesion could be traced ante mortem

To this end neurological information was gathered from each patient s case record and a special neurological examination was administered to many of the patients during the study itself Every patient received a series of preselected audiological tests Many of the patients also received a standardized vestibular examination The auditory and vestibular tests were usually performed on the same day in the laboratories of the Department of Otolaryngology and Maxillofacial Surgery Northwestern University Medical School The neurological examination was given in the same location within a day or two

II SUBJECTS

In this investigation 61 patients with multiple sclerosis were studied These individuals ranged in age from 20–64 years (with a mean age of 41 years) Thirty five were female and 26 were male Most of them were drawn from the Northwestern University Multiple Sclerosis Clinic and the remainder from referrals by private physicians Some patients have been tested more than once. In such instances, only the latest set of results on each patient is presented here

III NEUROLOGICAL EVALUATION

Neurological information was available for each of the cases reviewed here In a few instances, the neurological information was taken from case histories, hospital charts, or information provided by the referring physician All the other subjects received medical and neurological examinations at the Northwestern University Multiple Sclerosis Clinic and/or by Dr Vinod Sahgal, who was the neurologist participating in this study The neurological and other medical data on every patient were subsequently analyzed by Dr Sahgal He designated the foci where he inferred from the information at hand, that the patient possessed sclerotic lesions. These judgments regarding the location and extent of neural pathology were used later for evaluation of the auditory and vestibular findings that emerged from the study The neurological examination and inquiry were conducted in accordance with the format used in the collaborative study on the effects of ACTH on multiple sclerosis (Rose et al 1970) Briefly in this format a comprehensive history of the patient s symptomatology and medical background is obtained In addition checks are made of visual acuity and field abnormalities, of deep tendon and pathologic reflexes and of cranial nerve function Limb weakness, spasticity and coordination are explored Sensory deficits (vibratory position pain and touch) are also sought. Tests of gait are completed when possible Further examinations were completed as deemed necessary by Dr Sahgal

IV AUDIOLOGICAL EVALUATION

Each patient was given a battery of hearing tests in the Northwestern University Auditory

Research Laboratory (Medical School Branch). Whenever possible, all the tests reported below were administered, but special considerations in individual cases made it impossible always to do so. The number of times each test was given is reported in the results chapter. What follows in this section is a description of the several auditory tests and the rationale for including each one.

A. Pure tone audiometry

The evaluation started with conventional discrete frequency pure tone audiometry. This basic test provided data on subjects' hearing sensitivity across the frequency range from 125–8 000 Hz, on air-bone relationships in cases of loss in hearing sensitivity and on the configuration of impairment. Comparison of this configuration with the contours of loss generally associated with various auditory diseases allowed identification of instances where the auditory system had been coincidentally damaged by causes other than multiple sclerosis. In instances which exhibited such coincidental effects, the task was to estimate (from all the data at hand) the degree and configuration of hearing loss attributable to multiple sclerosis. One of the goals was to avoid assigning to multiple sclerosis any pure tone deficits which it had not produced. Fortunately since multiple sclerosis strikes most often in the young adult years, complicating coincidental pathology was absent in most cases.

B. Speech audiometry

Traditional measures of speech reception threshold (for spondees) and intelligibility of monosyllabic words [NU 6 version presented at 40 dB re SRT (Tillman & Carhart, 1966)] were obtained. These and all other speech test materials were stored on magnetic tape. Later 4 other speech tests were administered. In the first 3 of these, discrimination of monosyllables had to be made under more difficult listening conditions. In the fourth, spondees were the test items.

One test consisted of monosyllables (NU 6 version at 40 dB re SRT) presented monaurally and simultaneously with white noise. The S/N ratio was 0 dB. Dayal et al. (1966) found that 9 of 13 multiple sclerotic patients so tested experienced substantial breakdown in discrimination when they presented monosyllables in white noise at an S/N ratio of +10 dB. In our laboratory most normals score from 70 to 80% correct on this test. It has been our clinical experience that some persons with peripheral (cochlear or VIIIth nerve) involvements experience substantial difficulty with this test even though their speech discrimination in quiet for the test materials is excellent (90–100%). Discrimination of monosyllables in the presence of white noise also has been found to be substantially decreased in some patients with surgically confirmed temporal lobe lesions (Sinha, 1959).

A second test was designed to search for lesions at the brainstem level. It was a modification of the Matzker (1959) filtered speech test. NU6 monosyllables were recorded synchronously on 2 channels of a magnetic tape with pass-bands of 250–750 Hz on channel 1 and 1250–1750 Hz on channel 2. When normals were asked to integrate the 2 channels at a sensation level of +26 dB re SRT they scored about 80% correct irrespective of whether both channels were presented to 1 ear or 1 was administered via the right ear and the other via the left ear or vice versa. Breakdown on this test is generally accepted as being a clue to involvement of the auditory system in the brainstem (Matzker 1959). Preibish-Effenberger (1963) gave a Matzker-type test to 50 subjects with multiple sclerosis and found that 22 of them did not integrate the 2 channels normally.

The third special speech test employed competing messages. This test consisted of presentation of NU6 monosyllables at 50 dB SL to 1 ear while competing sentences were administered at 60 dB SL to the other ear. It is an easy listening task for most persons except for those with involvement of the auditory system at the cortical level. The usual score for normal hearers is between 90 and 100%. In other words, a listener can keep the two trains of stimuli iso-

IV AUDIOLOGICAL EVALUATION

Each patient was given a battery of hearing tests in the Northwestern University Auditory

excessively slow i.e., decruitment (Davis & Goodman, 1966). Recruitment, as defined in the auditory literature, describes a condition in which loudness growth in an impaired ear is considerably more rapid than in a companion normal ear. Decruitment, on the other hand, labels a situation in which thresholds are similar and normal bilaterally but in which at supra threshold levels, loudness experience is decreased in one ear as compared to the opposite ear.

The fifth special tonal test was the simultaneous binaural median plane localization (SBMPL) test. This test examines the lateralization capacity of the subject (de Bruine-Altes, 1946). The basic procedure of the SBMPL test is to present the same pure tone to both ears in phase and to vary the intensity of the stimulus to one ear until a fused image is perceived in the midline. The critical point is that the auditory system must be relatively intact within the brainstem in order for perceptual fusion (and hence lateralization) of the two stimuli to occur. A few isolated reports in the literature (e.g. Jerger 1960b) indicate that persons with brainstem lesions affecting the auditory system cannot achieve fusion. The typical manifestation in such instances is dramatic breakdown in the ability to localize the stimulus image.

The last special tonal test measured masking level differences (MLDs) for 500 Hz. The procedure employed was basically the same as used for the speech MLD test. The binaural threshold for 500 Hz in the presence of an 80 dB SPL narrow band noise centered at 500 Hz was obtained during homophasic presentation (both signals in phase interaurally) and during antiphasic reception (the tone out of phase and the noise in phase interaurally). The improvement in sensitivity resulting from transition to the antiphasic condition is the pure tone MLD. MLD phenomena have been extensively studied with normal subjects and sophisticated theories regarding the binaural mechanisms at work have been formulated (Durlach, 1963; Jeffress, 1965; Schenkel, 1967). With our test procedure (Bekesy tracking for the masked thresholds), 95 % of the persons in a large sample of normal hearers attained MLDs of 8 dB or greater with the mean 500 Hz MLD being 11.2 dB. Schoeny & Carhart (1971) found that MLDs for 500 Hz exhibited by patients with unilateral Menière's disease were reduced. They thus demonstrated that end-organ involvement on one side when matched with normal hearing on the other can somewhat disrupt the escape from masking which yields MLDs. No one has taken the next step, namely to ascertain how much MLDs for tones or speech are disrupted in persons with bilaterally normal sensitivity for pure tones and speech, but with central involvement. The present study represents an initial step in that direction.

V. VESTIBULAR EVALUATION

The functioning of the vestibular system of 44 of the 61 multiple sclerotic patients was examined by means of electronystagmography (ENG). A preselected sequence of tests was administered in the Vestibular Research Laboratory at Northwestern University Medical School under the guidance of one of the authors (Dr Cecil Hart) who also interpreted all of the resulting data.

A. Visually induced eye movements

The reasons for including tests of visually induced eye movements in the ENG examination were two. First, unless the visual and oculomotor systems were functioning normally analysis of the vestibulo-ocular reflex, as measured at the eye, might be open to error. Also much useful clinical information may be derived from a study of the visual and oculo-motor systems and of the vestibulo-ocular reflex since their function may be subject to a variety of modifications by various neurological mechanisms throughout their paths. Such information is particularly likely to appear in multiple sclerosis, where oculo-motor disturbances are encountered frequently. The following is a description of the tests for visually induced eye movements routinely carried out during the study.

lated from one another Tests of this type have been found useful in evaluating central auditory disorders (Jerger 1964) Breakdown in performance when it did occur was characterized by disruption of performance via the ear opposite the cortical lesion.

The last special speech test measured the masking level difference (MLD) for spondees (Carhart Tillman & Johnson 1966 Carhart Tillman & Dallos, 1968) Spondee thresholds in the presence of broad band noise at 80 dB SPL were determined under 2 binaural listening conditions The first was homophasic. Here both the noise and the speech were in phase with themselves at the 2 ears (S_0N_0) The second condition was antiphasic, i e., each word was now out of phase with itself at the two ears ($S_\pi N_0$) The MLD is the improvement in masked threshold observed during antiphasic listening. Under our test conditions the mean spondee MLD for normal hearers is 8 7 dB and 95 % achieve spondee MLDs of 6 or more dB The speech MLD test has not been used clinically but it was included in the present study because its outcome clearly depends on the adequacy of binaural neurological interactions which are central

C. Special pure tone tests

A series of 6 special tonal tests was also used

One of these was Carhart's (1957) threshold tone decay test. It was usually administered at 500 1 000 2 000 4 000 and 8 000 Hz. Normal behavior on the Carhart tone decay test is characterized by very little tone decay (Willeford 1960) Patients with end-organ lesion may perform similarly or may exhibit up to 30 dB of adaptation at higher frequencies Persons with active VIIIth nerve pathologies (Tillman 1969) and with brainstem lesions (Parker et al 1968) often exhibit adaptation much in excess of 30 dB A variation of the test measured tonal perversion i e., tone to-noise decay rather than tonal disappearance. Both phenomena were sought since Parker et al (1968) have demonstrated that some persons with multiple sclerosis show hyperadaptation of one type while others experience the second type

The second tonal test was Békésy audiometry (Jerger 1960*a* Owens, 1964) Fixed frequency threshold tracings of up to 3 minutes duration were obtained at 500 1 000 2 000 4 000, and 8 000 Hz. The relationship between the tracings for interrupted and continuous tones was used to assign each set of data to 1 of the 4 categories described by Jerger It will be recalled that the Type II pattern is most characteristic of cochlear lesions, while Types III and IV usually emerge when there are active VIIIth nerve lesions. The Type I configuration is ordinarily interpreted as resulting when both cochlear and VIIIth nerve functions are normal. Thus, the Type I pattern is expected both when there is no problem whatsoever and in some forms of central auditory involvement. However Parker et al (1968) have obtained Type III and Type IV tracings from patients with brainstem involvement.

The SISI test (Jerger et al., 1959) was administered at 1 000 2 000 and 4 000 Hz. It was utilized to assess the ability of the listener to detect small changes in stimulus intensity at 20 dB SL and at 85 dB HL. Positive SISI results, scores of 60% or higher obtained at 20 dB SL, are conventionally interpreted as an indication of cochlear involvement when there is sensorineural loss. Under similar circumstances, SISI scores of 30% or less are construed to denote retrocochlear involvement. Similarly low scores are expected from normal hearers or from persons with very mild hearing losses. If the SISI test is administered at 85 dB HL in such instances, high scores result Failure to obtain high scores under these circumstances has been found in cases of VIIIth nerve involvement Such findings are particularly striking when an individual fails to respond to increments of 2–5 dB during the SISI test at either of the presentation levels (Thompson 1963)

Fowler's alternate binaural loudness balance test [ABLB (Fowler 1928)] was given at 500 1 000 and 4 000 Hz. This test provides information about the loudness function of the auditory system i e whether growth in loudness is normal excessively rapid i e recruitment or

excessively slow i.e., decruitment (Davis & Goodman, 1966). Recruitment, as defined in the auditory literature, describes a condition in which loudness growth in an impaired ear is considerably more rapid than in a companion normal ear. Decruitment, on the other hand, labels a situation in which thresholds are similar and normal bilaterally but in which at suprathreshold levels, loudness experience is decreased in one ear as compared to the opposite ear.

The fifth special tonal test was the simultaneous binaural median plane localization (SBMPL) test. This test examines the lateralization capacity of the subject (de Bruine-Altes, 1946). The basic procedure of the SBMPL test is to present the same pure tone to both ears in phase and to vary the intensity of the stimulus to one ear until a fused image is perceived in the midline. The critical point is that the auditory system must be relatively intact within the brainstem in order for perceptual fusion (and hence lateralization) of the two stimuli to occur. A few isolated reports in the literature (e.g. Jerger 1960*b*) indicate that persons with brainstem lesions affecting the auditory system cannot achieve fusion. The typical manifestation in such instances is dramatic breakdown in the ability to localize the stimulus image.

The last special tonal test measured masking level differences (MLDs) for 500 Hz. The procedure employed was basically the same as used for the speech MLD test. The binaural threshold for 500 Hz in the presence of an 80 dB SPL narrow band noise centered at 500 Hz was obtained during homophasic presentation (both signals in phase interaurally) and during antiphasic reception (the tone out of phase and the noise in phase interaurally). The improvement in sensitivity resulting from transition to the antiphasic condition is the *pure tone MLD*. MLD phenomena have been extensively studied with normal subjects and sophisticated theories regarding the binaural mechanisms at work have been formulated (Durlach, 1963; Jeffress, 1965; Schenkel, 1967). With our test procedure (Békésy tracking for the masked thresholds), 95 of the persons in a large sample of normal hearers attained MLDs of 8 dB or greater with the mean 500 Hz MLD being 11.2 dB. Schoeny & Carhart (1971) found that MLDs for 500 Hz exhibited by patients with unilateral Ménière's disease were reduced. They thus demonstrated that end-organ involvement on one side when matched with normal hearing on the other can somewhat disrupt the escape from masking which yields MLDs. No one has taken the next step namely to ascertain how much MLDs for tones or speech are disrupted in persons with bilaterally normal sensitivity for pure tones and speech, but with central involvement. The present study represents an initial step in that direction.

V. VESTIBULAR EVALUATION

The functioning of the vestibular system of 44 of the 61 multiple sclerotic patients was examined by means of electronystagmography (ENG). A preselected sequence of tests was administered in the Vestibular Research Laboratory at Northwestern University Medical School under the guidance of one of the authors (Dr Cecil Hart) who also interpreted all of the resulting data.

A. Visually induced eye movements

The reasons for including tests of visually induced eye movements in the ENG examination were two. First, unless the visual and oculomotor systems were functioning normally analysis of the vestibulo-ocular reflex, as measured at the eye, might be open to error. Also, much useful clinical information may be derived from a study of the visual and oculo-motor systems and of the vestibulo-ocular reflex since their function may be subject to a variety of modifications by various neurological mechanisms throughout their paths. Such information is particularly likely to appear in multiple sclerosis, where oculo-motor disturbances are encountered frequently. The following is a description of the tests for visually induced eye movements routinely carried out during the study.

Fig 1a Absence of any baseline shift on opening and closing the eyes.

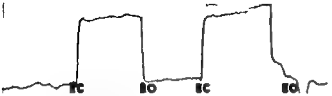

Fig 1b An example of (abnormal) baseline shift (35° to the left) on closing the eyes.

1 *Lateral gaze imbalance*

The test is performed by seating the patient erect in a chair and having him gaze at a marker on the wall in the direct line of vision The patient alternately opens and closes his eyes, and the ENG record is examined for a consistent sustained shift to one side or the other Examples of normal and abnormal test results are shown in Figs. *1a* and *b* In a similar test, Cogan (1948) found a deviation to occur in only 2% of normal subjects Patients with cerebral lesions showed an incidence of 72%, and a deviation was found in 84% of patients with brainstem and cerebellar lesions.

Although disturbances in lateral gaze may possibly occur at the level of the cortex the basal ganglia and the superior colliculi the major control of lateral gaze is probably at the level of the pons The so-called pontine center for conjugate lateral gaze is probably in the vicinity of the abducens nuclei for which reason it is sometimes called the parabducens center (Cogan 1956 Crosby 1953)

Cortical and labyrinthine control of lateral gaze is apparently also mediated through the centers in the vestibular nuclei concerned with horizontal gaze Thus a unilateral or asymmetrical lesion of any of these pathways or centers, either destructive or irritative, may upset the balance between the two systems and result in an imbalance in the centering mechanisms of the eye

Once the eyes are closed and the fixation reflex is eliminated, the eyes are free to adopt their resting position. Under normal circumstances the electrical ENG position should be midline, the Bell's phenomenon cancelling out bilaterally However if there is an imbalance between the 2 halves of the pathways and centers discussed above the eyes, and thus their common electrical axis, may come to rest off-center to some degree.

2. *Slow pursuit*

The test of slow pursuit movements is accomplished by requesting the patient to follow a black vertical stripe as it moves across his field of vision, first in 1 direction and then in the other inducing an eye speed of 5 /sec. An example of the record which results is shown in Fig. *2a* Pursuit movement abnormalities in multiple sclerosis have been documented by Henriksson et al (1969) and by von Noorden & Preziosi (1966) An example of abnormal pursuit is shown in Fig *2b*

3 *Pendulum tracking*

The patient is again seated erect and while keeping the head still follows with his eyes the motion of a pendulum suspended from the ceiling. The pendulum has an arc of about 30 as subtended from the patient's eyes, at a distance of about 3 meters, with an average frequency of about 4 cycles per second This task again repre-

Fig 2a. An example of normal pursuit eye movements (5 /sec).

Fig 2b. An example of abnormal pursuit eye movements (5°/sec).

Fig. 3a. An example of normal pendulum tracking.

Fig. 3b. An example of abnormal pendulum tracking.

sents a pursuit eye movement, although somewhat faster than the slow pursuit movement described above. Instead of being a pursuit at a constant velocity this test involves a constantly changing velocity of the eye, with reversal of direction at each half cycle.

In discussing abnormal pursuit ("step-wise" pursuit recordings), von Noorden & Preziosi (1966) reported finding this phenomenon in a selection of patients with various disease processes, all of which involved the cerebellum. For this reason, they associated this sign fairly specifically with cerebellar disease. Abnormal pursuit can be seen in many conditions, including Wilson's disease (Goldberg & von Noorden, 1966), strabismic amblyopia (von Noorden & Preziosi 1966), myotonic dystrophy (von Noorden, 1969), and brain concussion and cerebellopontine angle tumors (von Noorden & Preziosi, 1966). An example of normal pendulum tracking is shown in Fig. 3a and abnormal tracking in Fig. 3b.

Abnormalities of pendulum tracking in patients with multiple sclerosis were first noticed by Cords in 1930. He found such abnormalities in 34 % of his patients (18/60). This phenomenon also has been found by von Noorden & Preziosi (1966) in 66 % of their patients (10/15), and by Benitez (1970) in 78 % of his patients (54/69).

4. *Optokinetic nystagmus*

This test is performed with the patient seated erect and watching a large optokinetic drum with a diameter of 30 inches which is directly in the line of gaze and at a distance of about 3 feet. The drum itself is white, with thin black vertical lines. The drum is rotated, first in one direction, and then in the other such that the eye speed induced should be 20° per second. Examples of a normal and an abnormal trace are given in Figs. 4a and b.

Disturbances of optokinetic nystagmus may occur as a result of a variety of lesions, including damage to the pons and brainstem, areas which are quite frequently involved in multiple sclerosis. Cogan (1956) stated that "... lesions of the cerebellum and brainstem may produce disturbances of optokinetic nystagmus on one side, but the defective response is usually bilateral ..." (p. 201).

B. Spontaneous nystagmus

The second major procedure of the vestibular study involved a search for spontaneous nystagmus. A variety of nystagmic patterns may be seen in multiple sclerosis. The nystagmus may be either unidirectional or may change in direction with change in the direction of gaze (gaze nystagmus). The fast phase in this instance is usually in the direction of the deviation of the eye.

Pathological gaze nystagmus is commonly seen with lesions of the cerebellum and sometimes of the brainstem. It is quite often "fixation dependent" and may be either attenuated or totally eliminated by the application of Frenzel's

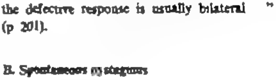

Fig. 4a. An example of normal optokinetic nystagmus.

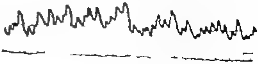

Fig. 4b. An example of abnormal optokinetic nystagmus.

Fig 1a Absence of any baseline shift on opening and closing the eyes.

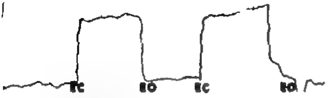

Fig 1b. An example of (abnormal) baseline shift (35 to the left) on closing the eyes.

1 Lateral gaze imbalance

The test is performed by seating the patient erect in a chair and having him gaze at a marker on the wall in the direct line of vision The patient alternately opens and closes his eyes and the ENG record is examined for a consistent sustained shift to one side or the other Examples of normal and abnormal test results are shown in Figs. 1*a* and *b* In a similar test Cogan (1948) found a deviation to occur in only 2% of normal subjects Patients with cerebral lesions showed an incidence of 72% and a deviation was found in 84% of patients with brainstem and cerebellar lesions.

Although disturbances in lateral gaze may possibly occur at the level of the cortex the basal ganglia and the superior colliculi, the major control of lateral gaze is probably at the level of the pons. The so-called pontine center for conjugate lateral gaze" is probably in the vicinity of the abducens nuclei for which reason it is sometimes called the parabducens center (Cogan 1956 Crosby 1953)

Cortical and labyrinthine control of lateral gaze is apparently also mediated through the centers in the vestibular nuclei concerned with horizontal gaze Thus a unilateral or asymmetrical lesion of any of these pathways or centers either destructive or irritative may upset the balance between the two systems and result in an imbalance in the centering mechanisms of the eye

Once the eyes are closed and the fixation reflex is eliminated the eyes are free to adopt their resting position Under normal circumstances, the electrical ENG position should be mid line the Bell s phenomenon cancelling out bilat erally However if there is an imbalance be tween the 2 halves of the pathways and centers discussed above the eyes, and thus their com mon electrical axis may come to rest off-center to some degree.

2. Slow pursuit

The test of slow pursuit movements is accomplished by requesting the patient to follow a black vertical stripe as it moves across his field of vision, first in 1 direction and then in the other inducing an eye speed of 5 /sec. An example of the record which results is shown in Fig. 2*a* Pursuit movement abnormalities in multiple sclerosis have been documented by Henriksson et al (1969) and by von Noorden & Preziosi (1966) An example of abnormal pursuit is shown in Fig. 2*b*

3 Pendulum tracking

The patient is again seated erect and while keeping the head still follows with his eyes the motion of a pendulum suspended from the ceil ing. The pendulum has an arc of about 30 as subtended from the patient s eyes, at a distance of about 3 meters with an average frequency of about 4 cycles per second This task again repre-

Fig 2a An example of normal pursuit eye movements (5°/sec).

Fig 2b An example of abnormal pursuit eye movements (5 /sec).

Fig 3a An example of normal pendulum tracking.

Fig 3b An example of abnormal pendulum tracking.

sents a pursuit eye movement, although somewhat faster than the slow pursuit movement described above Instead of being a pursuit at a constant velocity this test involves a constantly changing velocity of the eye, with reversal of direction at each half cycle.

In discussing abnormal pursuit ("step-wise" pursuit recordings), von Noorden & Preziosi (1966) reported finding this phenomenon in a selection of patients with various disease processes, all of which involved the cerebellum. For this reason, they associated this sign fairly specifically with cerebellar disease. Abnormal pursuit can be seen in many conditions, including Wilson's disease (Goldberg & von Noorden, 1966) strabismic amblyopia (von Noorden & Preziosi, 1966), myotonic dystrophy (von Noorden, 1969), and brain concussion and cerebellopontine angle tumors (von Noorden & Preziosi, 1966) An example of normal pendulum tracking is shown in Fig. 3a and abnormal tracking in Fig 3b

Abnormalities of pendulum tracking in patients with multiple sclerosis were first noticed by Cords in 1930 He found such abnormalities in 34 of his patients (18/60) This phenomenon also has been found by von Noorden & Preziosi (1966) in 66 of their patients (10/15), and by Benitez (1970) in 78 of his patients (54/69)

4 *Optokinetic nystagmus*

This test is performed with the patient seated erect and watching a large optokinetic drum with a diameter of 30 inches which is directly in the line of gaze and at a distance of about 3 feet. The drum itself is white, with thin black vertical lines. The drum is rotated, first in one direction, and then in the other such that the eye speed induced should be 20° per second. Examples of a normal and an abnormal trace are given in Figs. 4a and b

Disturbances of optokinetic nystagmus may occur as a result of a variety of lesions, including damage to the pons and brainstem, areas which are quite frequently involved in multiple sclerosis. Cogan (1956) stated that " lesions of the cerebellum and brainstem may produce disturbances of optokinetic nystagmus on one side, but the defective response is usually bilateral " (p 201).

B. *Spontaneous nystagmus*

The second major procedure of the vestibular study involved a search for spontaneous nystagmus. A variety of nystagmic patterns may be seen in multiple sclerosis. The nystagmus may be either unidirectional or may change in direction with change in the direction of gaze (gaze nystagmus) The fast phase in this instance is usually in the direction of the deviation of the eye

Pathological gaze nystagmus is commonly seen with lesions of the cerebellum and sometimes of the brainstem. It is *quite often* "fixation dependent" and may be either attenuated or totally eliminated by the application of Frenzel's

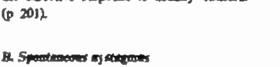

Fig 4a. An example of normal optokinetic nystagmus.

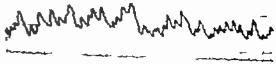

Fig 4b An example of abnormal optokinetic nystagmus.

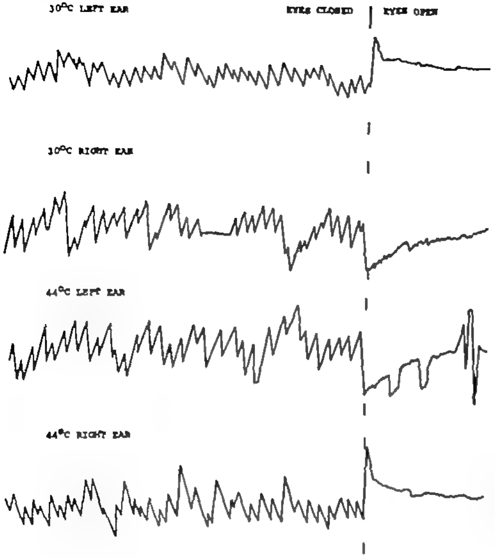

Fig 5a. An example of the normal attenuation effect engendered by opening of the eyes during the post caloric nystagmus.

(+20 diopter) convex lenses or by closing the eyes.

Unidirectional nystagmus i e always beating in the same direction when seen irrespective of the position of the eye is more suggestive of a lesion of the vestibular system proper and typically is attenuated or suppressed with ocular fixation In other words, the application of Frenzel s glasses or closing the eyes will render the nystagmus more intense It is only this latter nystagmus, recorded with the eyes closed, which is noted in this ENG analysis.

The actual recording was made with the patient seated erect with the head in the anatomical position and was made prior to the positional and caloric tests, which might induce some provoked nystagmus. A provoked spontaneous nystagmus is one that is present in the erect position not present at the beginning of the test sequence but which appears during the course of the ENG examination and persists after the normal physiologic duration of any antecedent vestibular stimulus effect has passed From a clinical point of view it has much the same significance as a spontaneous nystagmus, but of lesser degree

C Positional nystagmus

The third major portion of the electronystagmographic evaluation consisted of positional tests. Just as spontaneous nystagmus may be present only with the eyes open or with the eyes closed, so may positional nystagmus appear under varying conditions. Nystagmus may be "direction changing" beating in different direc

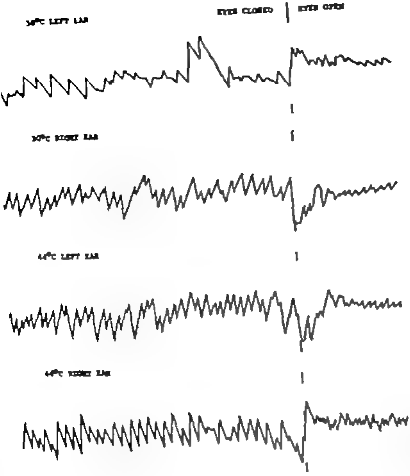

Fig 5b An example of abnormal (minimal) attenuation effect on opening of the eyes during the post-caloric nystagmus.

tions with different positions of the head or it may be "direction fixed" always beating in the same direction whenever it is elicited. The clinical implications of unidirectionality or multidirectionality are generally the same as for spontaneous nystagmus

Again, in the ENG analysis, recordings were made only with the eyes closed Although many positions are possible, the positions tested were with the patients supine, supine with the head rotated to the left, and supine with the head rotated to the right Each position was maintained for 1 minute

D Response to caloric stimulation

The final tests in the vestibular work-up were the caloric tests A modification of the Hallpike technique (Fitzgerald and Hallpike, 1942) was employed according to the recommendations of the ENG study group (Rubin, 1968)

The patient rests comfortably on an examination table, flexed at the hips such that the body and head are elevated 30° from the horizontal. Thus, there is no extension or flexion of the neck relative to the main axis of the trunk. The first 75 seconds of the caloric test sequence (30° and 44° irrigations of each ear canal) are recorded with the eyes closed, whereupon the patient is requested to open his eyes and fixate on a small light in the ceiling (Hart, 1967) Recording is continued in this modality until no more visible nystagmus can be seen by direct examination of the eyes. At this point, the patient is requested to close his eyes and the nystagmus is further

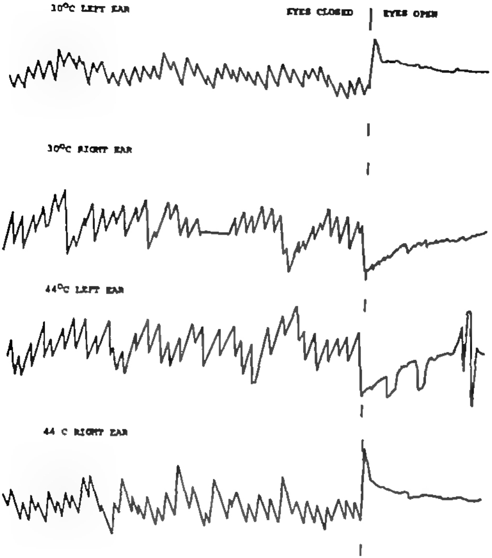

Fig 5a. An example of the normal attenuation effect engendered by opening of the eyes during the post caloric nystagmus.

(+20 diopter) convex lenses or by closing the eyes

Unidirectional nystagmus, i e., always beating in the same direction when seen irrespective of the position of the eye, is more suggestive of a lesion of the vestibular system proper and typically is attenuated or suppressed with ocular fixation In other words, the application of Frenzel s glasses or closing the eyes will render the nystagmus more intense It is only this latter nystagmus, recorded with the eyes closed which is noted in this ENG analysis.

The actual recording was made with the patient seated erect with the head in the anatomical position and was made prior to the positional and caloric tests, which might induce some provoked nystagmus A provoked spontaneous nystagmus is one that is present in the erect position, not present at the beginning of the test sequence, but which appears during the course of the ENG examination and persists after the normal physiologic duration of any antecedent vestibular stimulus effect has passed From a clinical point of view it has much the same significance as a spontaneous nystagmus but of lesser degree

C. Positional nystagmus

The third major portion of the electronystagmographic evaluation consisted of positional tests Just as spontaneous nystagmus may be present only with the eyes open or with the eyes closed so may positional nystagmus appear under varying conditions. Nystagmus may be direction changing" beating in different direc

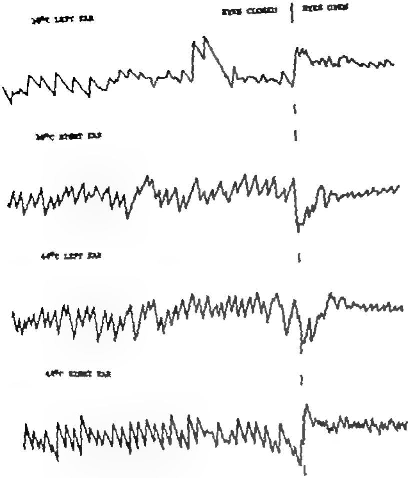

Fig. 5b. An example of abnormal (minimal) attenuation effect on opening of the eyes during the post-caloric nystagmus.

tions with different positions of the head, or it may be "direction fixed" always beating in the same direction whenever it is elicited. The clinical implications of unidirectionality or multidirectionality are generally the same as for spontaneous nystagmus.

Again, in the ENG analysis, recordings were made only with the eyes closed. Although many positions are possible, the positions tested were with the patients supine, supine with the head rotated to the left, and supine with the head rotated to the right. Each position was maintained for 1 minute.

D. Response to caloric stimulation

The final tests in the vestibular work-up were the caloric tests. A modification of the Hallpike technique (Fitzgerald and Hallpike, 1942) was employed, according to the recommendations of the ENG study group (Rubin, 1968).

The patient rests comfortably on an examination table, flexed at the hips such that the body and head are elevated 30° from the horizontal. Thus, there is no extension or flexion of the neck relative to the main axis of the trunk. The first 75 seconds of the caloric test sequence (30° and 44° irrigations of each ear canal) are recorded with the eyes closed, whereupon the patient is requested to open his eyes and fixate on a small light in the ceiling (Hart, 1967). Recording is continued in this modality until no more visible nystagmus can be seen by direct examination of the eyes. At this point, the patient is requested to close his eyes and the nystagmus is further

Fig 6 An example of dysrhythmic eye movements.

Fig 7 An example of the abnormal nystagmic be known as triangular waves.

recorded until there is no more nystagmus in the expected direction (as seen on the ENG)

Although DeManez (1968) has recommended an index of ocular fixation for this modification it was found difficult to apply during the present study Often the nystagmus with the eyes open was unmeasurable electronystagmographically because of its small amplitude Also not infrequently in some patients, no definite nystagmic pattern was seen with the eyes closed due to dysrhythmia or cortical suppression Therefore, somewhat arbitrarily when the recordings were capable of valid interpretation a reduction in the amplitude or slow phase velocity of less than 50% of the original level on opening the eyes, was considered abnormal Examples of normal and abnormal attenuation are shown in Figs *5a* and *b* In the analysis of the maximum slow phase velocity with the eyes closed the Jongkees formula (Jongkees 1964) was applied with upper limits of normality being 15% for left right difference and 19% for directional preponderance For the duration with eyes open normal limits of 30 sec and 40 sec as recommended by Fitzgerald & Hallpike (1942) were accepted for left right difference and directional preponderance respectively

Hyperexcitability as evaluated by the maximum slow phase velocity eyes closed was said to be present if any 2 of the 4 caloric responses averaged more than 30 per second slow phase velocity This phenomenon was designated as marked if any 2 responses averaged more than 50 per second Hyperexcitability as evaluated by duration eyes open was said to be present if any 2 responses averaged more than 3 min each.

Bilateral paresis was said to be present if the sum of the 4 maximum slow phase velocities was less than 40 /second

The diagnosis of dysrhythmia was made entirely on the basis of subjective clinical judgment as no reliable means of quantifying this phenomenon have been found Henriksson (personal communication) has suggested the integration of the time differences between successive nystagmic beats as a valid measure However the equipment to do this was not available An example of dysrhythmia is shown in Fig. 6

The records were also examined for the presence of triangular waves, which in essence, represent a slowing of the fast phase. Such waves might be considered to reflect a partial lesion of the center generating the fast phase of nystagmus Although there is some difference of opinion as to where the center may be many investigators feel that it is probably in the brainstem rostral to the vestibular nuclei Triangular waves are shown in Fig 7

Thus it may be seen that the ENG examination encompasses an evaluation not only of the peripheral labyrinth but also the brain stem area cerebellum, vestibular ocular pathways and certain aspects of the visual oculo-motor system Multiple sclerosis does not affect the peripheral labyrinth, but does affect the latter areas with a high degree of frequency Therefore the ENG examination is well suited for the evaluation of the lesions of these various interconnecting systems.

VI SUMMARY

The foregoing sections have described in some detail the neurological auditory and vestibular examinations administered to a large group of persons with multiple sclerosis Sixty-one patients were given the neurological and auditory evaluations The neurological examination followed the format described in a previous study

y Rose et al. (1970). The battery of auditory ests consisted of routine audiometric techniques nd a group of special tonal and speech tests ncluding some not previously employed with clinical populations. In addition, vestibular function for 44 of the 61 multiple sclerosis patients was examined utilizing electronystagmographic techniques.

Fig 6 An example of dysrhythmic eye movements.

Fig 7 An example of the abnormal nystagmic beat known as triangular waves.

recorded until there is no more nystagmus in the expected direction (as seen on the ENG)

Although DeManez (1968) has recommended an index of ocular fixation for this modification it was found difficult to apply during the present study Often the nystagmus with the eyes open was unmeasurable electronystagmographically because of its small amplitude Also not infrequently in some patients, no definite nystagmic pattern was seen with the eyes closed due to dysrhythmia or cortical suppression Therefore somewhat arbitrarily when the recordings were capable of valid interpretation a reduction in the amplitude or slow phase velocity of less than 50 % of the original level on opening the eyes, was considered abnormal Examples of normal and abnormal attenuation are shown in Figs *5a* and *b* In the analysis of the maximum slow phase velocity with the eyes closed the Jongkees formula (Jongkees 1964) was applied, with upper limits of normality being 15 % for left right difference and 19 % for directional preponderance. For the duration with eyes open, normal limits of 30 sec and 40 sec as recommended by Fitzgerald & Hallpike (1942) were accepted for left right difference and directional preponderance, respectively

Hyperexcitability as evaluated by the maximum slow phase velocity eyes closed was said to be present if any 2 of the 4 caloric responses averaged more than 30 per second slow phase velocity This phenomenon was designated as "marked if any 2 responses averaged more than 50° per second Hyperexcitability as evaluated by duration eyes open was said to be present if any 2 responses averaged more than 3 min each.

Bilateral paresis was said to be present if the sum of the 4 maximum slow phase velocities was less than 40 /second.

The diagnosis of dysrhythmia was made entirely on the basis of subjective clinical judgment as no reliable means of quantifying this phenomenon have been found Henriksson (personal communication) has suggested the integration of the time differences between successive nystagmic beats as a valid measure However the equipment to do this was not available An example of dysrhythmia is shown in Fig. 6.

The records were also examined for the presence of triangular waves which in essence, represent a slowing of the fast phase Such waves might be considered to reflect a partial lesion of the center generating the fast phase of nystagmus. Although there is some difference of opinion as to where the center may be, many investigators feel that it is probably in the brainstem rostral to the vestibular nuclei Triangular waves are shown in Fig 7

Thus it may be seen that the ENG examination encompasses an evaluation not only of the peripheral labyrinth but also the brain stem area cerebellum vestibular ocular pathways and certain aspects of the visual oculo-motor system Multiple sclerosis does not affect the peripheral labyrinth but does affect the latter areas with a high degree of frequency Therefore, the ENG examination is well suited for the evaluation of the lesions of these various interconnecting systems.

VI SUMMARY

The foregoing sections have described in some detail the neurological auditory and vestibular examinations administered to a large group of persons with multiple sclerosis Sixty-one patients were given the neurological and auditory evaluations. The neurological examination followed the format described in a previous study

Table I *Incidence (percentage) of selected neurological signs and symptoms for 61 patients with multiple sclerosis*

Signs and Symptomatology	
Spasticity and hyperreflexia	98
Sphincter disturbance and/or impotence	95

can group the subjects according to general site of lesion and extent of damage and then consider the auditory test data in light of these groupings. This is done later in the paper

II AUDIOLOGICAL FINDINGS

An abstract of the auditory tests administered to the 61 multiple sclerotics is given for each ear in Table III In the cases of the tone decay Békésy SISI ABLB, and SBMPL tests, the most note

Table II *Incidence (number of persons) of sites of lesion for 61 patients with multiple sclerosis inferred from neurological evaluation*

Level of lesion labelled as in Fig 8 Incidence of spinal cord involvement shown separately

Level	Number	Spinal cord incidence[a]
No neural signs	1	
1 (only)	1	
2 (only)	1	1
3 (only)		
4 (only)	8	7
1 and 3	1	1
1 and 4	8	3
2 and 4		1
3 and 4	2	2
1 2, and 3	9	6
1 2, and 4	2	1
1 3 and 4	1	1
2, 3, and 4	10	8
1 2, 3, and 4	8	3

Seven persons presented with only spinal cord signs

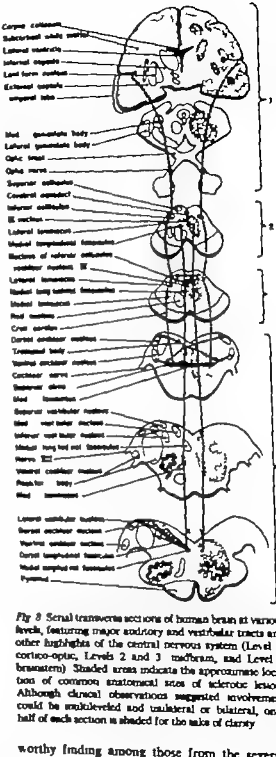

Fig 8 Serial transverse sections of human brain at various levels, featuring major auditory and vestibular tracts and other highlights of the central nervous system (Level 1 cortico-optic, Levels 2 and 3 midbrain, and Level 4 brainstem) Shaded areas indicate the approximate location of common anatomical sites of sclerotic lesion. Although clinical observations suggested involvement could be multileveled and unilateral or bilateral, only half of each section is shaded for the sake of clarity

worthy finding among those from the several frequencies tested is reported in the table. The findings that emerged are summarized below first for each test separately and then for rela-

3 Results

I NEUROLOGICAL FINDINGS

The neurological findings for the 61 subjects under study are given in Table I This table reports the incidence of certain neurological signs and symptoms encountered in this group of multiple sclerotic patients The amount of overlap in the *indicated percentages reveals the* multiple involvement of the disease process throughout the central nervous system of these patients From this table, it is apparent that assorted motor and cerebellar disturbances were most common in this group In addition medial longitudinal fasciculus (MLF) *syndrome* was evident in 54 % of the subjects paresthesias (60 %), diplopia and oscillopsia (50 %) optic atrophy (50 %), and gamma globulin elevation (46) were similarly prevalent. Auditory complaints as presenting symptoms were rare 7 %

The above stated figures are quite similar to earlier reports of incidences of findings in multiple sclerosis (e g. Carter et al 1950 Poser 1966) Thus this population appears to be typical

Table II details the neuroanatomical involvements which were judged by the neurologist to have been present in these patients Here the population is divided according to the inferred sites of lesions. This table should be studied in conjunction with Fig. 8 which was developed to assist in clarifying suspected sites of lesion The figure gives a schematic representation of *the auditory and vestibular tracts. Notice in the* figure that the central nervous system has been divided into 4 major levels representing the cortical and optic zone (level 1) the midbrain (2 and 3) and the brainstem (4) Within this schematic the major auditory and vestibular crossings and nuclei are labelled The right half of each section also contains stippled regions corresponding to sites of predilection for sclerotic foci It should be mentioned that the lesions may be extensive and *bilateral* The "level" column in Table II reports which of the levels shown in Fig. 8 were inferred to have been involved in the 61 patients. A separate column gives the number of cases who also had *symptoms referred to spinal cord lesions. Notice that* the neurological evaluations suggested that all but 8 of the 61 subjects had symptoms referrable to lesions at 1 or more of the levels depicted in Fig. 8 One of these 8 had no neurological symptoms at examination and the other 7 re*vealed symptomatology attributable to spinal cord damage. However it is of interest* that all 7 patients with only spinal cord symptoms at neurological evaluation yielded at least 1 noteworthy auditory finding.

One area of considerable interest is Level 4 wherein lies the central portions of the VIIIth cranial nerve the auditory and vestibular nuclei, and the trapezoid bodies. A total of 67 of the 61 subjects had symptoms thought due to lesions at this level of the CNS However 76 of the group with Level 4 lesions gave primarily cerebellar signs, *10 % had symptoms of purely low* brainstem (non-cerebellar) lesions and 14 had signs of both cerebellar and non-cerebellar Level 4 lesions. Lesions in the midbrain were inferred to be present in a considerable number of the subjects 51 were thought to have lesions in Level 3 52 in Level 2 Lesions thought present at the cortico-optic level were slightly less prevalent, 50 %. Symptoms attributable to spinal cord damage were observed in 67 of the subjects and 12 of the 61 subjects had only *spinal cord signs at the time* of the neurological examination

Not surprisingly many subjects gave evidence of wide-spread lesions in the CNS However one

tionships between tests Vestibular abnormalities and sites of lesion inferred from the neurological examinations are also presented in Table III

A Results for individual tests

1 *Pure tone thresholds and configurations*

The thresholds at the several test frequencies are not given in Table III Instead Column 5 of the table presents 2 types of information the configuration of the audiogram and whether or not a hearing loss was present at some point(s) across the frequency range The categories for the audiometric configuration conform to general usage (Carhart, 1945) except for the arched configuration [1]

Hearing loss is here defined as a pure tone threshold exceeding 25 dB hearing level (ANSI 1969) at one or more audiometric test frequencies in the 125–8 000 Hz range There were 64 ears (of a possible 122 ears) for which such a deficiency was found Of these 64 ears, 39 ears had no threshold exceeding 35 dB (a mild loss), 13 ears had at least one threshold in the range 40–65 dB and 12 ears had one or more thresholds which exceeded 65 dB

Twenty three persons (and thus 46 of 64 ears with hearing loss) had bilateral hearing losses. Fourteen of these persons had bilaterally symmetrical threshold configurations, but only 11 of them had bilaterally symmetrical and equally

[1] The arched configuration is characterized by better sensitivity for the mid-frequencies than for either low or high frequencies. The pattern is labelled arched because threshold sensitivity drops fairly symmetrically to poorer but not necessarily equal levels at both low and high frequencies. A variant of the arched configuration is the lazy S contour a threshold pattern also marked by best hearing in the mid frequencies, but in which the poorest threshold at the low frequency end occurs at 500 Hz, i e thresholds worsen from 125–500 Hz, improve in the mid-frequencies, and worsen again at higher frequencies. (However a clear lazy-S pattern was not observed in this sample of 122 ears) These patterns have been previously associated with multiple sclerosis (Bentzen et al 1951 Preibisch-Effenberger 1963 Dayal & Swisher 1967 Kehajov 1967 Chladek, 1968).

Mild 30–35 dB, moderate 40–65 dB severe 65 dB

Speech discrimination was measured at these levels unless otherwise specified in quiet @ 40 dB SL re SRT against contralateral speech competition @ 50 dB SL re SRT with (contralateral) competition at 60 dB SL re SRT (S/C = −10); in low noise (ipsilateral) @ 40 dB SL re SRT (S/N 0) filtered (monaural and binaural) @ 26 dB re relevant SRTs The filtered performance involved four scores and was graded N normal or A abnormal For explanations of normality and abnormality and further details on all of the speech procedures, see the text.

The tonal tests and the MLD for speech were administered in the usual fashion as was discussed in the text. The results listed in the table are the most outstanding at one or more frequencies in the specified ear except the results of loudness balancing (ABLB) were assigned to an ear when possible (i.e., in cases of decruitment) but were otherwise assigned to the person the binaural tests, median plane localization and masking level differences, were assigned to persons

The SISI results were graded I increased, D decreased, and N normal See the text

The code for ABLB was assigned as follows EE equal thresholds, equal rates of loudness growth ED = equal thresholds, decruitment (in the designated ear) UR unequal thresholds (10 dB), recruitment; UD unequal thresholds, decruitment, UN unequal thresholds, no recruitment

The code for SBMPL was assigned as follows EE equal thresholds, midline at equal intensities; EU equal thresholds, midline at unequal intensities (10 dB) EF equal thresholds, failed to experience midline, UE unequal thresholds (10 dB), midline at equal intensities, UU unequal thresholds, midline at unequal intensities, UF unequal thresholds, failed to experience midline

The MLDs represent the difference between thresholds in SoNo and Sπ No conditions See text.

( ) in tone decay results decay beyond equipment limits

The code for the vestibular abnormalities (see Table VI and explanation thereof) was assigned thusly A abnormal optokinetic tracking B abnormal pendulum tracking C positional nystagmus, D post-caloric hyperexcitability E poor or reversed attenuation effect, F unilateral paresis, G abnormal slow tracking, H dysrhythmia, I spontaneous nystagmus, J directional preponderance, and K lateral gaze imbalance

The inferred sites of lesion from the neurological evaluation correspond to Levels 1 (cortico-optic), 2 (midbrain at superior colliculus), 3 (midbrain at inferior colliculus), and 4 (brainstem at auditory and vestibular nuclei) in Fig. 8 An (S) in this column means that neurological signs of spinal cord lesion were present.

Could not operate hand switch

severe hearing losses It is interesting that of the multiple sclerotic patients with hearing loss in this sample, more had bilateral deficits than had unilateral deficits

Sensitivity of 25 dB HL or better at all frequencies was obtained via 58 ears. Such performance was listed as normal in Table III. Of course, it was possible for an audiogram in this

tionships between tests. Vestibular abnormalities and sites of lesion inferred from the neurological examinations are also presented in Table III

A. Results for individual tests

1 *Pure tone thresholds and configurations*

The thresholds at the several test frequencies are not given in Table III Instead Column 5 of the table presents 2 types of information the configuration of the audiogram and whether or not a hearing loss was present at some point(s) across the frequency range The categories for the audiometric configuration conform to general usage (Carhart 1945) except for the arched configuration.[1]

Hearing loss is here defined as a pure tone threshold exceeding 25 dB hearing level (ANSI 1969) at one or more audiometric test frequencies in the 125–8 000 Hz range There were 64 ears (of a possible 122 ears) for which such a deficiency was found Of these 64 ears, 39 ears had no threshold exceeding 35 dB (a mild loss), 13 ears had at least one threshold in the range 40–65 dB and 12 ears had one or more thresholds which exceeded 65 dB

Twenty three persons (and thus 46 of 64 ears with hearing loss) had bilateral hearing losses. Fourteen of these persons had bilaterally symmetrical threshold configurations, but only 11 of them had bilaterally symmetrical and equally

[1] The arched configuration is characterized by better sensitivity for the mid-frequencies than for either low or high frequencies. The pattern is labelled arched because threshold sensitivity drops fairly symmetrically to poorer but not necessarily equal levels at both low and high frequencies. A variant of the arched configuration is the lazy-S contour a threshold pattern also marked by best hearing in the mid-frequencies, but in which the poorest threshold at the low frequency end occurs at 500 Hz, i e thresholds worsen from 125–500 Hz, improve in the mid frequencies, and worsen again at higher frequencies (However a clear lazy-S pattern was not observed in this sample of 122 ears.) These patterns have been previously associated with multiple sclerosis (Bentzen et al 1951 Preibish-Effenberger 1963 Dayal & Swischer 1967 Kehajov 1967 Chladek 1968).

reduced correct discrimination by more than 10 %. Of the 8 ears with normal speech discrimination in quiet, but reduced discrimination in the competing message condition, 5 of 8 exhibited decreased performance exceeding 10 %. In 3 instances, the scores were dramatically reduced (34-76 %), and in 2 of these cases, the scores in quiet were normal.

Discrimination for monosyllables when white noise was present in the same ear was obtained from 115 ears. This procedure was administered with a S/N ratio of 0 dB at a presentation level of 40 dB re the relevant SRT. Normal hearers in similar circumstances obtain scores of 70-80 % correct. In contrast, scores below 60 % were attained 28 times in this sample of multiple sclerosis subjects. In addition, 9 persons of the 57 tested had an interaural disparity in correct response rate exceeding 10 % on this test, even though the scores for both ears were 60 % or better.

The filtered speech test was administered to 36 persons (72 ears). This test, it will be recalled, involved simultaneous presentation of 2 passbands (a low frequency band and a high frequency band) of lists of 50 monosyllabic words to the listener in 4 ways: both bands to the right ear, both bands to the left ear, low band pass to the left ear with high band pass to the right ear and vice versa. Results were interpreted separately for each ear of stimulus entry. Since normal hearers correctly identify about 80 % of the filtered monosyllables regardless of whether the task was a monaural one or a binaural one, scores below 60 % in any situation or differences between ears exceeding 10 % in monaural situations were considered abnormal. Eight of 36 persons who took the test showed abnormal behavior on it: 1 via both ears and the other 7 monaurally. The subject with binaurally aberrant behavior scored less than 60 % for all test conditions. The scores for the other 7 persons were all greater than 60 %, but the interaural difference exceeded 10 %.

4. *Threshold tone decay*

The Carhart threshold tone decay test was administered at 1 or more frequencies to 120 ears. Results are reported in Table III. In 82 instances, the amount of adaptation which was measured ranged between 0 and 30 dB at all frequencies tested. More threshold decay than this was classified as abnormal adaptation and occurred for at least 1 frequency in 38 ears involving 24 subjects,[1] i.e., there were 14 individuals with excess threshold tone decay bilaterally and 10 with excess decay in 1 ear. Via 20 of these ears, the adaptation elicited by the Carhart procedure was complete, i.e., beyond the limits of the test equipment. Of particular note is the fact that of the 12 subjects with complete tone decay, 8 had bilaterally complete tone decay.

All of the 18 ears with maximum threshold adaptation greater than 30 dB but not greater than 65 dB (and not exceeding the equipment limits) had thresholds of 35 dB or less at the frequencies with maximum decay, i.e., none had more than a mild loss of threshold sensitivity. All of the remaining 20 ears with abnormally large amounts of threshold tone decay had complete decay at 1 frequency or more. For 15 ears, the distance between threshold and the equipment limits was from 35-65 dB. Thresholds in these ears were: 0-25 dB for 6 ears, 30-35 dB for 7 ears, and 40-65 dB for 2 ears. Complete threshold tone decay in the other 5 ears meant decay exceeding 65 dB: 4 of these ears had thresholds of 0-25 dB and 1 of 30-35 dB.

5. *Békésy audiometry*

Fixed frequency Békésy audiometry administered to 115 ears, produced Type I traces via 34 ears. Type II traces emerged 62 times, Type III traces twice, and Type IV traces 17 times.

One of the interesting features of the Békésy data was the incidence of ongoing adaptation for the continuous tone threshold. Such "threshold drift" occurred in about half the tracings characterized as Type II and in about 70 % of

Significant tone-to-noise perversion (Parker et al. 1968) was not seen in this sample even though it was actively sought.

[1] There were 5 other ears showing decay beyond the equipment limits, but with overall measurable shifts of 20 dB or less. These ears must be classified as having an undetermined amount of threshold tone decay.

category to be irregular enough to be classified in a *configurational* category other than the flat category It turned out that 36 of the 58 audiograms of normal ears were flat and unremarkable The other 22 audiometric configurations grouped themselves as follows 11 arched configurations 7 rising configurations, and 4 notched configurations (3 of them below 3 000 Hz) Thus, the preponderance of normal but irregular audiograms was characterized by slightly poorer thresholds for low frequencies than for either mid or high frequencies Air and bone conduction curves were interweaving for all of these cases

The audiometric patterns from the 64 ears exhibiting hearing losses were classified as follows when the severity of loss is categorized by the worst pure tone threshold in this scheme the term "mild reflects thresholds of 30 or 35 dB hearing level the label "moderate represents thresholds from 40 to 65 dB HL, and the term severe is used to classify thresholds in excess of 65 dB

1 arched 17 ears—7 mild 5 moderate 5 severe
2. gradually falling 12 ears—5 mild 3 moderate, 4 severe
3 sharply falling 1 ear—moderate
4 flat 3 ears—2 mild 1 severe
5 notched—below 3 000 Hz 5 ears—mild
notched—at 3 000 Hz or higher 9 ears—4 mild 3 moderate 2 severe
6 high frequency loss at 3 000 Hz or higher 9 ears—8 mild 1 moderate
7 rising 8 ears–mild

Considering the threshold configurations from all 122 ears together the distribution of audiometric contours was (1) arched—28 ears (2) gradually falling—12 ears (3) sharply falling—1 ear (4) flat—39 ears (5) notched below 3 000 Hz—8 ears notched at 3 000 Hz or higher —10 ears (6) high frequency loss at 3 000 Hz or higher—9 ears and (7) rising—15 ears.

Thus, in this sample of 61 subjects, high frequency drop-off with or without low frequency involvement, was most common However a substantial fraction showed poorer thresholds for low than for mid frequencies. Moreover the arched pattern, not common in other populations appeared in 28 ears

Another way of viewing the audiometric findings is to consider the sensitivity exhibited in the so-called speech range (500–2 000 Hz) The next column in this table (column 7) reports by ear the pure tone averages across this range As one would expect from the review of audiometric configurations and thresholds, the preponderant majority of these 61 multiple sclerotic subjects showed good hearing across this range. Specifically only 15 of the 122 ears tested had pure tone averages for 500–2 000 Hz which exceeded 25 dB HL and only 4 ears had average hearing levels of 40 dB or poorer

2 Speech reception thresholds

Another conventional index of general auditory sensitivity is the speech reception threshold (SRT) Such thresholds were obtained for 121 ears (One subject would not tolerate suprathreshold testing through 1 ear) In only 6 instances (ears) did the speech reception threshold exceed 25 dB and in only 2 was it 40 dB or poorer

3 Speech discrimination scores

Discrimination for phonemically balanced monosyllables (NU 6) in a quiet situation at 40 dB SL was measured via 121 ears. In only 9 instances were the resultant scores below the 90% correct level

The competing message test was administered to 54 subjects (108 ears) In this test monosyllables were delivered to 1 ear at a sensation level of 50 dB re its SRT and sentences were delivered to the other ear at 60 dB sensation level re its SRT i e a signal/competition (S/C) ratio of −10 dB at opposite ears Normal listeners, when confronted by these conditions achieve scores from 90–100 %, that is, they duplicate their scores in quiet Scores less than 90 % correct were attained only 15 out of 108 times. Discrimination scores in quiet were also reduced via 7 of these ears, and for 4 of them, the presence of a contralateral competing message further

the 2-letter code used for SBMPL, the first letter always represents the relationship between thresholds in the 2 ears. As before, (E) stands for equal thresholds (within 10 dB) and (U) stands for unequal ones (>10 dB). The second letter of the code gives information about the localization judgment itself namely whether a midline experience was achieved at equal (E) intensities to the ears, at unequal (U) intensities to the ears, or whether the subject failed (F) to secure a median plane localization. The SBMPL results are recorded in the right ear row but pertain to both ears.

The results for the 60 persons to whom the SBMPL test was administered were as follows EE 38 EU-5, EF 5 UE 10 UU-2, and UF-0. Of special interest, of course, were the 10 individuals with similar thresholds in the 2 ears who could achieve no midline experience or achieved said experience with unequal intensities at the ears and the 2 individuals with unequal thresholds who achieved said experience with different intensities at the 2 ears.

9 *Masking level differences (MLDs)*

MLDs were obtained for conditions utilizing both 500 Hz tones and spondaic words as the test stimuli. Recall that the masking level difference was secured by comparing the amount of masking produced at 500 Hz or for spondees by noise (narrow band noise, 80 dB SPL overall level, for 500 Hz, wide band noise 80 dB SPL overall level for spondees) under 2 conditions (1) with the noise in phase with itself and the test stimulus in phase with itself at the 2 ears (S_0N_0), versus (2) with the noise in phase with itself but the test stimulus 180 out of phase with itself at the ears ($S_\pi N_0$).

One column of Table III gives the MLDs in dB for 500 Hz and the next for spondees. Twenty three of these subjects (almost half) had MLDs at 500 Hz of 7 dB or less. These results must be judged as abnormal since 95 of the control population (50 normal hearers) on which the test was calibrated had MLDs of 8 dB or more (mean 11 2 dB). Forty-two subjects took the spondee MLD test. Five-sevenths of them (30 persons) achieved MLDs of 5 dB or less. These MLDs must also be considered abnormally small since 95% of the control population obtained MLDs greater than 5 dB (mean = 8 7 dB). Therefore the 2 masking level difference tests proved to be items on which unusual auditory performance was quite consistently exhibited by the multiple sclerotic subjects under study.

B. Relationships among audiological results

The individual performances of the 61 multiple sclerotic patients shown in Table III revealed various permutations among test results. A topic of primary interest was that of determining what clustering of performances characterized the data for the entire group. Table IV supplies information on this topic. This table presents 776 comparisons in the form of fractions. The denominator indicates the number of instances under consideration at the moment. The numerator reports the number exhibiting the performance trait in question.

This method is used to report 2 sets of relationships. The 29 italicized fractions indicate the number of times that a single test was given (denominator) and the instances among these where performance was noteworthy (numerator)[1] For example, the italicized ratio in Row 1 reveals that 15 *ears of the* 122 ears tested had PTAs exceeding 25 dB, in Row 2 that 8 ears of 121 ears tested had SRTs exceeding 25 dB etc. The remaining 749 fractions show the degree to which noteworthy results appeared concurrently on 2 tests. The denominator reports the instances in which a patient who showed noteworthy results for 1 test (indicated by the row) also took the second test (indicated by the column). The numerator designates the number (of such instances) where behavior was also noteworthy on the second test. For example, in Row 1 note that of the 15 ears with PTAs exceeding 25 dB SRTs were also obtained from 14 of them, and 6

1 In some instances, the numerator indicates a specific pattern of response, such as a Type I Békésy tracing, rather than an abnormal response.

those classified as Type IV traces. In such instances, the separation between the interrupted and continuous tone thresholds usually increased steadily as a function of time up to the maximum *3 minute test limit In the case of the Type II* classification the separation of the tracings for the interrupted and continuous tones did not exceed 20 dB over the 3 minute time period whereas a separation in excess of 20 dB was observed for those tracings labelled Type IV

6 *Short increment sensitivity index (SISI)*

In Table III scores on the SISI task are divided into 3 groups according to the type of responsiveness shown As with other tests, what is reported in the table is the most revealing response when more than 1 type was given at different test frequencies via the same ear by the same subject A score of 60 % correct or better for 1 dB increments at 20 dB SL was classified as evidencing increased sensitivity and was coded (I) Fourteen ears (of the 117 ears tested) achieved such scores. A normal (N) score indicates less than 60 % correct responsiveness to 1 dB increments at 20 dB SL and 60 % or higher correct responses at 85 dB HL when threshold sensitivity was 35 dB or better Fifty-one ears allowed scores of this sort A classification of decreased sensitivity (D) was assigned to ears which could not recognize greater than 1 dB increments at 20 dB SL and/or could not correctly recognize 55 % or more of the 1 dB increments at 85 dB HL. Fifty two ears fell into this category on the SISI test

7 *Alternate binaural loudness balance (ABLB)*

The results of the ABLB task are shown for each person in Table III in terms of the following 2 letter codes The first letter of each pair gives information about thresholds in the 2 ears, namely whether they were equal (E—within 10 dB) or unequal (U—greater than 10 dB disparity) The second letter gives information about the intensity levels at which equal loudness was experienced namely whether such levels suggested recruitment (R) when the thresholds were unequal (U) decruitment (D) when the thresholds were equal (E) or unequal (U), no recruitment (N) when thresholds were unequal (U) or whether the intensity levels producing equal loudness were equal (E) when the thresholds were equal (E) All combinations but EE were placed in the row of results for the ear in which the pertinent loudness experience was judged to occur i e recruitment, decruitment and no recruitment were assigned to a particular ear When equal loudness was experienced at equal intensities in ears with equal thresholds (EE), the 2 letter code was placed in the right ear row but pertains to both ears.

Recruitment and no recruitment were defined according to the criteria suggested by Jerger (1962) Decruitment was defined as an abnormally slow rate of loudness growth in an ear whose threshold was 25 dB or better and whose threshold was similar to that of the ear against which the balance was performed Specifically when the achievement of equal loudness in ears with similar and normal thresholds required more than 10 dB greater intensity in 1 of those ears, the ear needing the additional intensity was assumed to be decruiting (see Davis & Goodman 1966) The opposite hypothesis, that the other ear was recruiting despite its normal threshold was rejected as untenable because it is less likely that at high signal levels, the stimulus to this other ear was abnormally loud than it is that the stimulus to the first ear was perceived at reduced loudness

Thirty seven persons with equal thresholds judged equally intense tones to be equally loud 11 others, however behaved in a manner suggesting decruitment in 1 of the ears Eleven persons had different thresholds in the 2 ears at the test frequencies 8 of these showed recruitment and 3 showed no recruitment Two persons could not be tested

8 *Simultaneous binaural median plane localization (SBMPL)*

The SBMPL test was administered to 60 persons and the results are reported in Table III by means of a system of coding the results that is similar to the one used for the ABLB test In

…atients with multiple sclerosis

In all rows and columns except those for ABLB, SBMPL, and MLD results, N number of ears tested In the ABLB, SBMPL, and MLD row and columns, N number of persons tested The table is most easily read by row The coding in the column and row headings is done in the same manner as explained in the text and detailed in footnotes to Table III.

The italicized fraction in each row is the ratio of abnormal or otherwise noteworthy results for the indicated test to the sample size for that test The other fractions in each row give incidences of noteworthy results on pairs of tests These other fractions are based on the number of noteworthy results (numerator) in the italicized ratio I the remainder of the ratios answer the question "Of the ears that yielded noteworthy results on test X, how many also yielded noteworthy results on test Y?" Of course, the denominator of these ratios does not always reflect the total number who performed in noteworthy fashion on test X, since some of them were not administered test Y

For example, in the first row PTAs were established for 122 ears and were abnormal (exceeded 25 dB) in 15 of the 122 ears (the italicized ratio). Continuing in the first row the remaining ratios are concerned only with these 15 abnormal ears and are read as follow SRT were obtained from 14 of the 15 ears, and for 6 of the 14, the SRT was also abnormal (exceeded 25 dB) Still in Row 1 note that discrimination for speech was tested in 14 of the 15 ears of interest, and that 4 of the 14 had scores below 90 %. Moving to Row 9 (tone decay 30 dB), observe that threshold tone decay exceeded 30 dB of the 120 ears tested (the italicized ratio in Row 9). The rest of the ratios in Row 9 deal only with the 38 ears with tone decay of 38 had PTAs 25 dB, 1 of 38 had an SRT > 25 dB, etc.

In all rows and columns except those for ABLB, SBMPL, and MLD results, N = number of ears tested. In the ABLB, SBMPL, and MLD rows and columns, N = number of persons tested. The table is most easily read by rows. The coding in the column and row headings is done in the same manner as explained in the text and detailed in footnotes to Table III.

The italicized fraction in each row is the ratio of abnormal or otherwise noteworthy results for the indicated test to the sample size for that test. The other fractions in each row give incidences of noteworthy results on pairs of tests. These other fractions are based on the number of noteworthy results (numerator) in the italicized ratio, i.e. the remainder of the ratios answer the question "Of the ears that yielded noteworthy results on test X, how many also yielded noteworthy results on test Y?" Of course, the denominator of these ratios does not always reflect the total number who performed in a noteworthy fashion on test X, since some of them were not administered test Y.

For example, in the first row, PTAs were established for 122 ears and were abnormal (exceeded 25 dB) in 15 of the 122 ears (the italicized ratio). Continuing in the first row, the remaining ratios are concerned only with these 15 abnormal ears and are read as follows: SRTs were obtained from 14 of the 15 ears, and for 8 of the 14, the SRT was also abnormal (exceeded 25 dB). Still in Row 1, note that discrimination for speech was tested in 14 of the 15 ears of interest, and that 4 of the 14 had scores below 90 %. Moving to Row 9 (tone decay > 30 dB), observe that threshold tone decay exceeded 30 dB in 38 of the 120 ears tested (the italicized ratio in Row 9). The rest of the ratios in Row 9 deal only with the 38 ears with excess tone decay, e.g. 2 of 38 had PTA > 25 dB, 1 of 38 had an SRT > 25 dB, etc.

Table V *Incidence (percentage) of abnormal auditory test results and pairs of abnormal auditory test results for 61 patients with multiple sclerosis*

The percentages given above are derived from the fractions in Table IV. See the footnotes in Table IV and the text for explanation of the difference between italicized and non-italicized fractions and for the manner in which the table can be read. See Table for the coding in the column and row headings.

1 *Pure tone hearing loss*

Marked pure tone hearing loss was not common in this population It was mentioned earlier that fully 60% of the ears tested had no pure tone loss exceeding 35 dB, i.e. exceeding a mild hearing loss. Furthermore, 88% had pure tone averages (PTAs) of 25 dB or better Interestingly of those multiple sclerosis patients with some hearing loss, 57% had deficits which were bilateral.

Of the ears with PTAs exceeding 25 dB half had equally deficient SRTs, but few had discrimination for speech in quiet below 90 correct. Most of the special speech and tonal test results for ears with PTAs > 25 dB were not those classically associated with retrocochlear lesion to illustrate, in most cases tone decay was minimal, loudness balancing demonstrated either equal rates of loudness growth or recruitment, median plane localization was achieved at equal intensity levels to the ears, Békésy traces were Type II, and so on However it would be a mistake, as is discussed later to assume that these findings suggested in all these cases that there was a coincident lesion which affected auditory responsiveness, but was unrelated to multiple sclerosis

2 *Speech discrimination*

Traditional speech testing, the determination of SRTs and of discrimination for monosyllables in quiet settings, revealed so little abnormality (only 5 of the SRTs were greater than 25 dB and only 7 of the speech discrimination scores were below 90 correct) that analysis of concurrent deficits on other tests is in many instances meaningless However 2 points of importance can be established All ears with SRTs 25 dB also had PTAs 25 dB Most also performed poorly on other special speech tests

Competing message test scores were below 90 correct for 14 of the ears tested, even though PTAs and SRTs were almost never abnormal Furthermore, in half the instances in which the competing message scores were decreased speech discrimination in quiet was normal In almost all cases of poor performance on the competing message task, difficulty was also encountered on the speech in white noise test. Breakdown also occurred half the time during filtered speech testing. These ears were further characterized by abnormal threshold adaptation, decreased SISI scores, and abnormally small MLDs. Of potential special interest in this group of results were those 8 occasions when there was breakdown on the competing message task even though speech discrimination in quiet was normal These latter cases were characterized by the same pattern of test results as those just detailed for the entire group.[1]

Discrimination scores for speech in white noise were less than 60% for one-fourth of the ears tested. In addition, 16% of the time, scores differed by more than 10% between the 2 ears of the subjects. Thus, in total, 40% of the ears tested were unable to deal normally with speech when noise was simultaneously presented to the same ear In terms of total number then, performance on this test was the most frequently defective of all the monaural speech tests as well as 1 of the most frequently abnormal of all tests. When reduced speech in white noise scores were obtained, PTAs or SRTs rarely exceeded 25 dB and only 28 of the time was the speech discrimination score in quiet less than 90%. The most common abnormal results to occur in combination with reduced speech in white noise scores were unusual adaptation, decreased SISI scores, and reduced MLDs. In addition, about half of these ears also performed poorly on competing message tasks and one-fourth exhibited decruitment. As a last comment, it is worth noting that although reduced speech in white noise scores usually occurred via ears which exhibited most of the pattern of results discussed above, in some instances such reduction was accompanied only by abnormal scores on other difficult speech tests and occasionally

1 many of the instances of breakdown on competing message tests, noise competition was substituted for the standard sentence material, e.g. broad spectrum noise, speech spectrum noise, etc., at similar S C ratios. In all instances where this was done speech discrimination returned to the degree of excellence obtained in quiet settings.

by decruitment i e by signs of high level, CNS lesions

Filtered speech scores were abnormal for 12 % of the ears tested These cases were characterized by normal pure tone thresholds, speech reception thresholds and speech discrimination in quiet Breakdown also occurred half the time on other difficult speech tests when materials were presented through these ears Abnormal adaptation loudness balance or median plane localization results were not characteristic. Half of these subjects had pure tone MLDs smaller than 8 dB and all had abnormally small speech MLDs.

3 *Threshold tone decay*

Threshold tone decay exceeding 30 dB was exhibited via 32% of the ears tested Slightly over half of these instances represented adaptation beyond the equipment limits at some frequency More persons with tone decay had bilateral deficits than had unilateral ones, but almost none of the ears via which decay appeared had pure tone thresholds exceeding a mild loss of hearing, i e , exceeding 35 dB The high incidence of threshold tone decay especially bilateral tone decay and the fact that almost never was marked pure tone hearing loss associated with such decay were 2 of the particularly interesting auditory characteristics of this multiple sclerosis population

Individuals exhibiting excess decay generally performed normally via the same ear on regular and filtered speech discrimination tests. In one fourth of these instances, scores below 90 % were obtained on the competing message task About half the time an abnormal number of monosyllables was misunderstood when noise was presented to the same ear On tonal tests subjects prone to excess threshold tone decay showed same ear adaptation on the Békésy task (about half giving Type II traces and about half giving Type IV traces) decreased responsiveness to SISI increments, a 30 % incidence of decruitment (when hearing sensitivity was normal bilaterally) or no recruitment (despite unilateral hearing loss) variable SBMPL results, a 50 in-cidence of reduced masking level differences at 500 Hz, and small MLDs for speech.

4 *Békésy audiometry*

Békésy audiometry also revealed auditory adaptation Of particular interest is the fact that 15 of the ears yielded Type IV tracings and that another 54% gave Type II traces For only 2 ears, 2% of the population were Type III tracings noted despite the fact that threshold tone decay beyond the equipment limits was much more common Half of the Type II and IV traces featured ongoing, gradual adaptation of the continuous tone threshold As was the case with the tone decay findings less than 10 of the ears with Type II III and IV Békésy traces had significant pure tone hearing loss.

In those instances where tracings were classified Type IV threshold tone decay exceeded 30 dB about 90% of the time Behavior on the speech tests and the other tonal tests was like that described for the ears with excess threshold tone decay

Type II Békésy traces were generally observed when PTAs, SRTs, and speech discrimination in quiet were normal In a significant percentage (33%) of the ears through which Type II traces were obtained the speech in white noise scores were reduced A smaller group experienced difficulty with competing message speech (18 %) One-fourth had excess tone decay and one half had reduced MLDs. Loudness balancing and median plane localization results were generally normal but the SISI results were mixed half were normal, one-third were decreased and one sixth were increased

Type I Békésy tracings were generally associated with normal auditory behavior on all but the MLD tests

5 *SISI*

Most SISI scores fell into the 2 categories of normal and decreased response in about equal numbers. Only 12 of the scores were classified as increased In all these latter instances the ears involved had thresholds exceeding 25 dB at

one frequency 7 had mild hearing losses, 5 bespoke moderate losses, and 1 had a severe loss

The ears through which normal SISI scores were obtained, 44% of those tested, performed as follows on other tests PTAs and SRTs were 25 dB or better discrimination for monosyllables both in quiet and in difficult circumstances was normal 80% had tone decay less than 30 dB Békésy tracings were Type I or Type II median plane localization was achieved in a normal fashion, and pure tone MLDs were usually (7) normal. Interestingly one-fourth of the ears allowing normal SISI scores had decruitment (the rest balanced loudness equally) and two-thirds had reduced masking releases when spondees were the stimulus

When decreased scores on the SISI task were found (44 of the ears tested), more abnormal results were observed on other tests PTAs, SRTs, and speech discrimination in quiet were generally normal 27 performed abnormally in competing message situations 50 had difficulty interpreting speech in white noise 42 demonstrated threshold tone decay exceeding 30 dB and about 70 had Type II or Type IV Békésy tracings. Of the persons whose ears achieved decreased SISI scores, 27 revealed decruitment, 27 achieved midline images at unequal intensity levels or achieved no central image at all, over 57 had abnormally small MLDs at 500 Hz, and 76 had abnormally small MLDs for spondees

6 ABLB

Findings indicating decruitment (when both ears had normal and similar thresholds) or no recruitment (when there was a unilateral threshold deficit) were more common (24) than were results suggestive of recruitment (14) Decruitment w usually associated with abnormal performance on the speech in white noise test (54) threshold tone decay exceeding 30 dB (54), Type II or IV Békésy traces (77), and decreased SISI scores (54) Many of the persons with decruitment achieved normal midline experiences on the SBMPL task (73), but had abnormally small MLDs at 500 Hz (67%) and for speech (88%).

Although decruitment and reduced scores on competing message speech tests are both considered indicators of temporal lobe lesion (in the absence of evidence of more peripheral pathology) and although both occurred in about the same number of ears in this sample, the 2 findings as a combination were observed only twice

7 SBMPL

Of the 60 persons who were administered the SBMPL test, 80 had similar thresholds in the 2 ears for the frequencies tested Of these, 20% either could not achieve a midline image or achieved said image only when an interaural intensity difference that exceeded 10 dB was established All 12 persons with unequal thresholds at frequencies where the test was given achieved central images, 10 of them did so when equal intensities were delivered to both ears and 2 did so only when the stimuli were presented at different intensity levels to the 2 ears.

Persons who achieved a median plane experience when equally intense tones were delivered to their ears generally did well on regular pure tone and speech tests They also had little trouble with difficult speech tests, yielded Type II Békésy traces, had tone decay of 30 dB or less had normal or increased SISI scores (although 48 had decreased scores), judged equally intense tones as being equally loud, had normal pure tone MLDs, and yielded small speech MLDs.

Persons who did not experience a midline sensation or who did so only when tones of differing intensities were presented to the ears performed as follows on other tests. 20 had speech discrimination below 90% in quiet, 33 below 60 in noise 17 below 90 in a competing message situation, and 14 performed abnormally on the filtered speech test 43 had threshold tone decay exceeding 30 dB 36% yielded Type II Békésy tracings and 17 gave Type IV tracings 82 had decreased SISI scores 30 demonstrated decruitment or no recruitment 80 had unusually small MLDs for

by decruitment, i e by signs of high level CNS lesions.

Filtered speech scores were abnormal for 12 % of the ears tested These cases were characterized by normal pure tone thresholds, speech reception thresholds and speech discrimination in quiet Breakdown also occurred half the time on other difficult speech tests when materials were presented through these ears. *Abnormal adaptation*, loudness balance or median plane localization results were not characteristic. Half of these subjects had pure tone MLDs smaller than 8 dB and all had abnormally small speech MLDs.

3 *Threshold tone decay*

Threshold tone decay exceeding 30 dB was exhibited via 32 % of the ears tested Slightly over half of these instances represented adaptation beyond the equipment limits at some frequency More persons with tone decay had bilateral deficits than had unilateral ones but almost none of the ears via which decay appeared had pure tone thresholds exceeding a mild loss of hearing, i.e exceeding 35 dB The high incidence of threshold tone decay especially bilateral tone decay and the fact that almost never was marked pure tone hearing loss associated with such decay were 2 of the particularly *interesting auditory characteristics of this multiple* sclerosis population

Individuals exhibiting excess decay generally performed normally via the same ear on regular and filtered speech discrimination tests In one fourth of these instances, scores below 90 % were obtained on the competing message task About half the time an abnormal number of monosyllables was misunderstood when noise was presented to the same ear On tonal tests subjects prone to excess threshold tone decay showed same ear adaptation on the Békésy task (about half giving Type II traces and about half giving Type IV traces) decreased responsiveness to SISI increments a 30 incidence of decruitment (when hearing sensitivity was normal bilaterally) or no recruitment (despite unilateral hearing loss) variable SBMPL results a 50 in cidence of reduced masking level differences at 500 Hz, and small MLDs for speech.

4 *Békésy audiometry*

Békésy audiometry also revealed auditory adaptation Of particular interest is the fact that 15 of the ears yielded Type IV tracings and that another 54 % gave Type II traces For only 2 ears 2 % of the population, were Type III tracings noted despite the fact that threshold tone decay beyond the equipment limits was much more common Half of the Type II and IV traces *featured ongoing, gradual adaptation of the* continuous tone threshold As was the case with the tone decay findings, less than 10 of the ears with Type II III and IV Békésy traces had significant pure tone hearing loss.

In those instances where tracings were classified Type IV threshold tone decay exceeded 30 dB about 90 % of the time. Behavior on the speech tests and the other tonal tests was like that described for the ears with excess threshold tone decay

Type II Békésy traces were generally observed when PTAs, SRTs, and speech discrimination in quiet were normal In a significant percentage (33 %) of the ears through which Type II traces were obtained, the speech in white noise scores were reduced *A smaller group experienced dif*ficulty with competing message speech (18 %) One-fourth had excess tone decay and one-half had reduced MLDs. Loudness balancing and median plane localization results were generally normal but the SISI results were mixed half were normal one-third were decreased and one-sixth were increased

Type I Békésy tracings were generally associated with normal auditory behavior on all but the MLD tests.

5 *SISI*

Most SISI scores fell into the 2 categories of normal and decreased response in about equal numbers. Only 12 % of the scores were classified as *increased* In all these latter instances the ears involved had thresholds exceeding 25 dB at

None of these had an associated spontaneous nystagmus. Three had a positional nystagmus, eyes closed, direction fixed, beating to the same side as the shift, and 3 other patients had a caloric directional preponderance, again to the same side as the shift. There were none with a positional nystagmus or directional preponderance beating away from the side of the shift.

2. *Slow tracking*

Forty percent of the patients showed abnormalities of tracking, either some irregularity, ataxia, or saccades.

3. *Pendulum tracking*

In this series, abnormalities of pendulum tracking were found in 55% of the individuals.

4. *Optokinetic nystagmus*

Fifty-five percent of the patients performed poorly on this test. In all instances of faulty tracking but 2, the abnormalities were bidirectional.

B. Spontaneous nystagmus, eyes closed

Thirty-three percent of the patients had a spontaneous nystagmus: in 9 instances the beating was to the left and in 5 cases, the direction of the nystagmus was to the right.

C. Positional nystagmus, eyes closed

Half of the 38 patients given this test were free from positional nystagmus. In the 19 instances where it occurred, it was direction-fixed 16 times and direction-changing 3 times.

D. Caloric tests

Evaluation of the maximum slow phase velocity, eyes closed, revealed a relative unilateral paresis in 41 and a directional preponderance in 33 %. As evaluated by duration, eyes open, there was a unilateral paresis in 7 and a directional preponderance in 11. (The latter two values are not shown in Table VI because of the infrequency of their occurrence.)

Caloric hyperexcitability as evaluated by the maximum slow phase velocity was seen in 48 % of the patients, being marked in 11%. When the durations were considered, there was a 14% incidence of hyperexcitability. (Again, the latter value is not given in Table VI.)

Dysrhythmia of the post-caloric nystagmus, usually most manifest with the eyes open, occurred for 34% of the subjects, and an impairment in attenuation of the nystagmus on opening the eyes during the caloric tests was found in 41%.

Triangular waves were seen in only 1 case in this series. (Absence of the fast phase of caloric nystagmus is sometimes associated with the medial longitudinal fasciculus syndrome but no examples were encountered here.)

IV. SUMMARY

Neurological examinations of the 61 multiple sclerosis patients participating in this study revealed symptoms of widespread lesions throughout the central nervous system, particularly in the brainstem and adjacent midbrain regions. Comparison of this sample with others reported in the literature indicated that the present group was typical of the multiple sclerosis population.

Auditory evaluations, which included routine and current special auditory tests as well as some auditory tasks not heretofore employed clinically, demonstrated a marked diversity of auditory aberrations. These abnormalities were most commonly elicited by tests requiring response to a sustained stimulus, by tests requiring discrimination of speech in conditions other than quiet, and by binaural masking tests.

Vestibular examinations utilizing electronystagmography showed a variety of noteworthy results. Abnormal visually induced eye movements, positional nystagmus, and hyperexcitability in response to caloric stimulation were the most common findings.

500 Hz, and 89 % had unusually small MLDs for speech

8 *MLDs*

Recall that masking level differences were abnormally small at both 500 Hz and for spondees for a large proportion of this sample of multiple sclerosis patients 49 % of them yielded reduced MLDs at 500 Hz, 71 % attained reduced MLDs for spondaic words This rate of abnormality was one of the greatest for any of the auditory tests employed in the test battery

Fewer than 25 of the subjects with abnormally small MLDs at 500 Hz had PTAs or SRTs exceeding 25 dB Their speech discrimination in quiet was usually good but 33 % broke down in competing message situations and 54 % had difficulty with speech discrimination when noise was also present in the same ear About twice as many (65 % vs. 34 %) had 30 dB or less threshold tone decay as had decay greater than 30 dB About one-fourth of the persons with small pure tone MLDs had Type III or IV Békésy traces nearly half had Type II tracings SISI scores were mostly (54 %) decreased Loudness balancing yielded normal results for half the persons tested one-third showed decruitment or no recruitment and one-fifth exhibited recruitment SBMPL findings were unremarkable for half but two-fifths of the subjects could not achieve a midline image or did so in a manner suggesting faulty binaural processes. Finally 9 of every 10 persons with a small 500 Hz MLD also had a small speech MLD

The same general pattern that held for the 500 Hz MLD results vis a vis the other test findings also held for the speech MLD results. Of special interest are the facts that of the subjects yielding small speech MLDs, 27 % performed poorly on the SBMPL task and 68 % had small 500 Hz MLDs

III VESTIBULAR FINDINGS

Forty-four of the 61 patients in this study underwent the ENG examinations described earlier Almost all of these 44 patients took the entire battery although there were several instances where a few tests had to be omitted for such reasons as general debility of the patient or the status of the ear drum (thin scarred etc.). The results which are outlined in Table VI are reported as the respective percentages of abnormalities for patients given each test The general trends in these results are reviewed in a moment. For the reader who is interested a more detailed look at the vestibular findings for each patient is presented in Table III In this table readers can examine more carefully all the results for each patient. To facilitate such an examination, the vestibular signs presented in Table VI in the order they are listed have been assigned successive letters of the alphabet (A–K) Therefore, the column reporting these signs in Table III contains letters representing the appropriate sign (A) being indicative of abnormal optokinetic tracking and so on through (K) being representative of lateral gaze imbalance

Table VI *Incidence (percentage) of vestibular abnormalities for 44 patients with multiple sclerosis who were given ENG examinations*

The code designation was assigned to facilitate interpretation of Table III

Description	Per centage	Code designation
Abnormal optokinetic	55	A
Abnormal pendulum	55	B
Positional nystagmus	50	C
Hyperexcitability	48	D
Poor attenuation	41	E
Unilateral paresis	41	F
Abnormal slow tracking	40	G
Dysrhythmia	34	H
Spontaneous nystagmus	33	I
Directional preponderance	33	J
Lateral gaze imbalance	16	K

A. Visually induced eye movements

1 *Lateral gaze imbalance*

Only 16 of the patients had a shift of 10 or greater of the electrical axis of the eyes on changing from the eyes open, gaze ahead to the eyes closed gaze direction uncontrolled modality

None of these had an associated spontaneous nystagmus. Three had a positional nystagmus, eyes closed, direction fixed, beating to the same side as the shift, and 3 other patients had a caloric directional preponderance again to the same side as the shift. There were none with a positional nystagmus or directional preponderance beating away from the side of the shift.

2. *Slow tracking*

Forty percent of the patients showed abnormalities of tracking, either some irregularity ataxia, or saccades.

3 *Pendulum tracking*

In this series, abnormalities of pendulum tracking were found in 55 of the individuals.

4 *Optokinetic nystagmus*

Fifty-five percent of the patients performed poorly on this test. In all instances of faulty tracking but 2, the abnormalities were bidirectional

B. Spontaneous nystagmus, eyes closed

Thirty-three percent of the patients had a spontaneous nystagmus in 9 instances the beating was to the left and in 5 cases, the direction of the nystagmus was to the right

C. Positional nystagmus, eyes closed

Half of the 38 patients given this test were free from positional nystagmus In the 19 instances where it occurred, it was direction-fixed 16 times and direction-changing 3 times.

D Caloric tests

Evaluation of the maximum slow phase velocity eyes closed, revealed a relative unilateral paresis in 41 and a directional preponderance in 33 As evaluated by duration, eyes open, there was a unilateral paresis in 7 and a directional preponderance in 11 . (The latter two values are not shown in Table VI because of the infrequency of their occurrence)

Caloric hyperexcitability as evaluated by the maximum slow phase velocity was seen in 48 of the patients, being marked in 11 . When the durations were considered there was a 14 incidence of hyperexcitability (Again, the latter value is not given in Table VI.)

Dysrhythmia of the post-caloric nystagmus usually most manifest with the eyes open, occurred for 34 of the subjects, and an impairment in attenuation of the nystagmus on opening the eyes during the caloric tests was found in 41 .

Triangular waves were seen in only 1 case in this series. (Absence of the fast phase of caloric nystagmus is sometimes associated with the medial longitudinal fasciculus syndrome but no examples were encountered here)

IV SUMMARY

Neurological examinations of the 61 multiple sclerosis patients participating in this study revealed symptoms of widespread lesions throughout the central nervous system, particularly in the brainstem and adjacent midbrain regions. Comparison of this sample with others reported in the literature indicated that the present group was typical of the multiple sclerosis population.

Auditory evaluations, which included routine and current special auditory tests as well as some auditory tasks not heretofore employed clinically demonstrated a marked diversity of auditory aberrations. These abnormalities were most commonly elicited by tests requiring response to a sustained stimulus, by tests requiring discrimination of speech in conditions other than quiet, and by binaural masking tests.

Vestibular examinations utilizing electronystagmography showed a variety of noteworthy results. Abnormal visually induced eye movements, positional nystagmus, and hyperexcitability in response to caloric stimulation were the most common findings.

500 Hz and 89 had unusually small MLDs for speech.

8 *MLDs*

Recall that masking level differences were abnormally small at both 500 Hz and for spondees for a large proportion of this sample of multiple sclerosis patients 49 % of them yielded reduced MLDs at 500 Hz, 71 % attained reduced MLDs for spondaic words This rate of abnormality was one of the greatest for any of the auditory tests employed in the test battery

Fewer than 25 % of the subjects with abnormally small MLDs at 500 Hz had PTAs or SRTs exceeding 25 dB Their speech discrimination in quiet was usually good but 33 % broke down in competing message situations and 54 % had difficulty with speech discrimination when noise was also present in the same ear About twice as many (65 % vs 34 %) had 30 dB or less threshold tone decay as had decay greater than 30 dB About one-fourth of the persons with small pure tone MLDs had Type III or IV Békésy traces nearly half had Type II tracings SISI scores were mostly (54 %) decreased Loudness balancing yielded normal results for half the persons tested one third showed decruitment or no recruitment and one fifth exhibited recruitment. SBMPL findings were unremarkable for half but two-fifths of the subjects could not achieve a midline image or did so in a manner suggesting faulty binaural processes Finally 9 of every 10 persons with a small 500 Hz MLD also had a small speech MLD

The same general pattern that held for the 500 Hz MLD results vis a vis the other test findings also held for the speech MLD results Of special interest are the facts that of the subjects yielding small speech MLDs, 27 performed poorly on the SBMPL task and 68 % had small 500 Hz MLDs

III VESTIBULAR FINDINGS

Forty four of the 61 patients in this study underwent the ENG examinations described earlier Almost all of these 44 patients took the entire

Table VI *Incidence (percentage) of vestibular abnormalities for 44 patients with multiple sclerosis who were given ENG examinations*

The code designation was assigned to facilitate interpretation of Table III

Description	Percentage	Code designation
Abnormal optokinetic	55	A
Abnormal pendulum	55	B
Positional nystagmus	50	C
Hyperexcitability	48	D
Poor attenuation	41	E
Unilateral paresis	41	F
Abnormal slow tracking	40	G
Dysrhythmia	34	H
Spontaneous nystagmus	33	I
Directional preponderance	33	J
Lateral gaze imbalance	16	K

battery although there were several instances where a few tests had to be omitted for such reasons as general debility of the patient or the status of the ear drum (thin scarred etc). The results, which are outlined in Table VI are reported as the respective percentages of abnormalities for patients given each test. The general trends in these results are reviewed in a moment. For the reader who is interested a more detailed look at the vestibular findings for each patient is presented in Table III In this table, readers can examine more carefully all the results for each patient To facilitate such an examination, the vestibular signs presented in Table VI in the order they are listed have been assigned successive letters of the alphabet (A–K) Therefore, the column reporting these signs in Table III contains letters representing the appropriate sign (A) being indicative of abnormal optokinetic tracking and so on through (K) being representative of lateral gaze imbalance

A. Visually induced eye movements

1 *Lateral gaze imbalance*

Only 16 % of the patients had a shift of 10 or greater of the electrical axis of the eyes on changing from the eyes open gaze ahead to the eyes closed gaze direction uncontrolled modality

one of these had an associated spontaneous nystagmus. Three had a positional nystagmus, eyes closed, direction fixed beating to the same side as the shift, and 3 other patients had a alone directional preponderance, again to the same side as the shift. There were none with a positional nystagmus or directional preponderance beating away from the side of the shift.

Slow tracking

Forty percent of the patients showed abnormalities of tracking, either some irregularity ataxia, or saccades.

Pendulum tracking

In this series, abnormalities of pendulum tracking were found in 55% of the individuals.

Optokinetic nystagmus

Fifty-five percent of the patients performed poorly on this test. In all instances of faulty tracking but –, the abnormalities were bidirectional

B. Spontaneous nystagmus, eyes closed

Thirty-three percent of the patients had a spontaneous nystagmus in 9 instances the beating was to the left and in 5 cases, the direction of the nystagmus was to the right.

C. Positional nystagmus, eyes closed

Half of the 38 patients given this test were free from positional nystagmus In the 19 instances where it occurred it was direction-fixed 16 times and direction-changing 3 times.

D. Caloric tests

Evaluation of the maximum slow phase velocity eyes closed revealed a relative unilateral paresis in 41 % and a directional preponderance in 33 %. As evaluated by duration, eyes open, there was a unilateral paresis in 7% and a directional preponderance in 11 (The latter two values are not shown in Table VI because of the infrequency of their occurrence.)

Caloric hyperexcitability as evaluated by the maximum slow phase velocity was seen in 48 % of the patients, being marked in 11 %. When the durations were considered there was a 14 incidence of hyperexcitability (Again, the latter value is not given in Table VI)

Dysrhythmia of the post-caloric nystagmus, usually most manifest with the eyes open occurred for 34 of the subjects, and an impairment in attenuation of the nystagmus on opening the eyes during the caloric tests was found in 41 %.

Triangular waves were seen in only 1 case in this series. (Absence of the fast phase of caloric nystagmus is sometimes associated with the medial longitudinal fasciculus syndrome, but no examples were encountered here)

IV SUMMARY

Neurological examinations of the 61 multiple sclerosis patients participating in this study revealed symptoms of widespread lesions throughout the central nervous system, particularly in the brainstem and adjacent midbrain regions. Comparison of this sample with others reported in the literature indicated that the present group was typical of the multiple sclerosis population

Auditory evaluations, which included routine and current special auditory tests as well as some auditory tasks not heretofore employed clinically demonstrated a marked diversity of auditory aberrations. These abnormalities were most commonly elicited by tests requiring response to a sustained stimulus, by tests requiring discrimination of speech in conditions other than quiet, and by binaural masking tests.

Vestibular examinations utilizing electronystagmography showed a variety of noteworthy results. Abnormal visually induced eye movements, positional nystagmus, and hyperexcitability in response to caloric stimulation were the most common findings.

4 Discussion

I INTRODUCTION

The foregoing resumé of results emphasizes the complexity of the picture presented by the symptomatology of multiple sclerosis even when the individual fluctuations that occur with passing time are not included in the data As would be expected given the variability of multiple sclerosis consistent interrelations among symptoms do not always characterize the clinical population This complexity makes interpretation of results such as these very difficult. Nonetheless, trends appear which warrant analysis Therefore the task in this chapter is to interpret the trends that appeared in the audiological data and to relate them to the other findings at hand

The first fact to be borne in mind is that neurological examinations revealed most of our 61 subjects to have sclerotic involvement referable to the medulla and/or higher Thus, pathology at levels close to those occupied by the central auditory system had been indirectly demonstrated for many of these individuals and involvement of the central auditory system is a likelihood in some of them Second the authors re-emphasize that this population was typical of other multiple sclerosis populations discussed in the literature and that it was selected only on the basis of the certainty of diagnosis

One must also recall that the lesions of multiple sclerosis are limited to the central nervous system Thus while the most peripheral auditory lesion this disease can cause is in the root of the VIIIth nerve there is a series of more central and of higher level sites in the auditory system which may be involved In consequence of this consideration one must be cautious when interpreting audiological data not to jump too quickly to the assumption that the findings gathered here have the same meaning as they would have if they were the result of more peripheral causes, including VIIIth nerve tumors

One does well to remind himself that independently caused peripheral auditory lesions will be happenstance concomitants of multiple sclerosis in some cases but that these instances will not be frequent because multiple sclerotic patients are predominantly young adults. Study of the audiometric configurations, a detailed history and review of the medical records for each case convinced the authors that coincidental peripheral hearing involvements in this sample were rare One should of course, be on the lookout for such concomitance of pathology but one should also be ready to attribute a high prevalence of any auditory symptoms among multiple sclerosis patients to the neurological disorder rather than to an unusual concentration of such happenstances

The plan in this chapter is first to take a general look at some relationships between the auditory findings and other test results and then to look more specifically at each of the auditory tests.

II AUDITORY RESULTS IN RELATION TO NEUROLOGICAL FINDINGS

The incidence of cortical midbrain, and brain stem lesions in this particular population has been discussed in detail in Chapter 3 Each individual's profile of inferred neurological abnormalities has been carefully drawn in an attempt to establish the validity of the claim that the auditory results should be examined in light of known CNS damage It is abundantly evident that such damage did indeed exist in this sample given the incidence of MLF syndrome optic atrophy diplopia and oscillopsia and so on as detailed in Tables I and II

If one examines the incidence of abnormal auditory responsiveness as a function of the clinically inferred extent and level of neurological insult (as localized during neurological evaluations in the four general levels of the CNS portrayed in Fig. 8), it is quite clear that the extent of damage within the CNS has a demonstrable effect on the probability of abnormal auditory behavior. The main relationships are summarized in Table VII which gives the percentages of noteworthy auditory results associated with various combinations of inferred sites of lesion found in the population under study. Each percentage given in the table is the proportion of the patients given that test who exhibited the characteristic in question. Remember that not all subjects took every test. The neurological levels (1–4) referred to in the table are those defined and detailed in Fig. 8, Table II, and the discussions thereof. The grouping of levels into 4 general categories was necessary because sample size per category would otherwise have been too small, e.g., for this reason, all patients with signs thought referrable to Levels 1, 2, or 3 are in a single category. Recall, however, that population size for all combinations of neurological signs in this sample was given in Table II so that more specific comparisons can be made by referring to it.

The features of importance that emerge from Table VII are summarized below.

The incidence of auditory abnormalities cannot be attributed solely to lesions within the low brainstem, i.e. Level 4. For example, the typical auditory findings for the 8 persons with lesions only in Level 4 were normal pure tone and speech thresholds, no problems with difficult speech, normal SISI scores, normal loudness balancing, minimal adaptation in most instances, etc. The frequent observation of Type II Békésy tracings and reduced speech MLDs were the noteworthy findings for this subgroup. However, if one considers the 12 subjects with symptoms attributed to Level 4 and the (adjacent) midbrain, Levels 3 and sometimes 2, a higher incidence of abnormality was detected: 36% had difficulty with speech in white noise, 50% revealed threshold tone decay exceeding 30 dB, 4?% yielded Type II and 25% Type IV Békésy traces, 50% achieved low SISI scores, 41% demonstrated decruitment (or no recruitment despite unilateral hearing loss), 56% had abnormally small MLDs at 500 Hz, and 75% obtained unusually small MLDs for spondees. Even more dramatic were the findings from the 12 individuals whose symptoms suggested lesions only at the midbrain or higher in the CNS, i.e., in Levels 1 and/or 2 and/or 3. This population had incidences of abnormality (as defined throughout the paper) for the indicated tests as follows: competing message speech—33%, speech in white noise—40%, filtered speech—50%, excess threshold tone decay—64%, Type II Békésy tracings—64%, Type IV Békésy traces—18%, decreased SISI scores—60%, small 500 Hz pure tone MLDs—50%, and small speech MLDs—83%.

Widespread damage within the CNS, inferred from symptoms attributed to lesions in Levels 1, 2, 3 and 4 is more likely to result in auditory dysfunction than is spotty damage, i.e. lesions at non-adjacent levels such as Levels 1 and 3, 2 and 4, etc. For example, if one compares the 8 patients with lesions attributed to Levels 1–4 with those 14 with lesions at non-adjacent levels, auditory abnormality was much more prevalent in the group with widespread disorders: 38% had pure tone averages exceeding 25 dB, 38% could not correctly discriminate speech in quiet, 50% had difficulty with competing speech messages, 50% could not normally interpret filtered speech, 63% erred excessively on speech in white noise, 50% had excess threshold tone decay, 57% gave Type II Békésy tracings, 29% yielded *Type IV Békésy* traces, 63% obtained decreased SISI scores, 38% showed decruitment, [illegible] had small pure tone MLDs, and 100% had small *speech MLDs*. On the other hand, subjects with symptoms judged due to damage at scattered nonadjacent levels yielded incidences of abnormality exceeding 30% on only the Békésy task (50% Type II, 21% Type IV), SISI test (64% decreased), and speech MLD (64% abnormally small).

Eight of the 61 multiple sclerotic patients in

4 Discussion

I INTRODUCTION

The foregoing resumé of results emphasizes the complexity of the picture presented by the symptomatology of multiple sclerosis even when the individual fluctuations that occur with passing time are not included in the data As would be expected given the variability of multiple sclerosis, consistent interrelations among symptoms do not always characterize the clinical population. This complexity makes interpretation of results such as these very difficult. None theless trends appear which warrant analysis Therefore the task in this chapter is to interpret the trends that appeared in the audiological data and to relate them to the other findings at hand

The first fact to be borne in mind is that neurological examinations revealed most of our 61 subjects to have sclerotic involvement referrable to the medulla and/or higher Thus, pathology at levels close to those occupied by the central auditory system had been indirectly demonstrated for many of these individuals and involvement of the central auditory system is a likelihood in some of them Second the authors re-emphasize that this population was typical of other multiple sclerosis populations discussed in the literature and that it was selected only on the basis of the certainty of diagnosis.

One must also recall that the lesions of multiple sclerosis are limited to the central nervous system Thus, while the most peripheral auditory lesion this disease can cause is in the root of the VIIIth nerve there is a series of more central and of higher level sites in the auditory system which may be involved In consequence of this consideration one must be cautious when interpreting audiological data not to jump too quickly to the assumption that the findings gathered here have the same meaning as they would have if they were the result of more peripheral causes, including VIIIth nerve tumors

One does well to remind himself that independently caused peripheral auditory lesions will be happenstance concomitants of multiple sclerosis in some cases, but that these instances will not be frequent because multiple sclerotic patients are predominantly young adults. Study of the audiometric configurations, a detailed history and review of the medical records for each case convinced the authors that coincidental peripheral hearing involvements in this sample were rare One should of course be on the lookout for such concomitance of pathology but one should also be ready to attribute a high prevalence of any auditory symptoms among multiple sclerosis patients to the neurological disorder rather than to an unusual concentration of such happenstances

The plan in this chapter is first to take a general look at some relationships between the auditory findings and other test results, and then to look more specifically at each of the auditory tests

II AUDITORY RESULTS IN RELATION TO NEUROLOGICAL FINDINGS

The incidence of cortical midbrain and brainstem lesions in this particular population has been discussed in detail in Chapter 3 Each individual s profile of inferred neurological abnormalities has been carefully drawn in an attempt to establish the validity of the claim that the auditory results should be examined in light of known CNS damage It is abundantly evident that such damage did indeed exist in this sample given the incidence of MLF syndrome optic atrophy diplopia and oscillopsia, and so on as detailed in Tables I and II

the present study did not exhibit signs of any neurological involvement either in the brainstem or above it. One of these persons had no neurological signs whatsoever at the time he was seen for our study. His auditory responses were all normal except for the fact that the audiometric configuration for his left ear was arched and he yielded Type II Békésy tracings. The remaining 7 subjects gave evidence of spinal multiple sclerosis. Every one of these persons responded unusually on a few of the auditory tests and the circumstances were such that these responses did not seem to be due to happenstance concomitant peripheral ear pathology. Five of the 7 exhibited decreased sensitivity on the SISI test, 4 obtained abnormally small MLDs, 4 had trouble with speech discrimination in white noise, 3 had arched audiograms, 2 yielded both Type IV Békésy tracings and excess threshold tone decay. 1 had difficulty with the competing speech and filtered speech tests.

The last row in Table VII gives the percentage of noteworthy auditory results obtained from the sample of 7 patients with spinal multiple sclerosis. Although the sample size is small and extensive comment is therefore unjustified, some mention should be made of the mostly normal behavior of these 7 subjects. However, the exceptions to such normality are most interesting. In fact, 1 prominent feature of the group of 7 subjects who had only spinal signs of multiple sclerosis is that auditory behavior was aberrant as often as it was. It seems reasonable to suppose that this behavior was sometimes caused by *higher level neurological lesions which did not manifest themselves during neurological examination*. It should be noted that the auditory profile for 5 of these 7 persons was not particularly dramatic, i.e. auditory dysfunction was subtle and restricted. However, one subject yielded excess threshold tone decay and Type IV Békésy tracings despite normal function on other auditory tests. A second patient showed a number of markedly abnormal auditory findings including excess adaptation and sharply reduced performance on all difficult speech tests. Thus, here is a strong indication that after one has

Table VIII. *Incidence (percentage) of noteworthy auditory results[a] as a function of the number of inferred sites of neurological lesion[b] for 61 patients[c] with multiple sclerosis*

Number of sites of inferred lesion	PTA 25 dB	SRT > 25 dB	Speech discrimination < 90 %	Competing speech < 90	Speech in white noise < 60 %	Filtered speech abnormal	Tone decay 30 dB	Tone decay > 30 dB	Békésy Type I	Békésy Type II	Békésy Type III	Békésy Type IV	SISI Increased	SISI Decreased	SISI Normal	ABLB EE	ABLB ED	ABLB UR	ABLB UD	ABLB UN	SBMPL EE	SBMPL EU	SBMPL EF	SBMPL UE	SBMPL UU	SBMPL UP	500 Hz MLD 8 dB	Speech MLD < 6 dB
T levels or less (N = 30)	13	3	3	10	1	16	70	[illegible]	21	66	0	14	13	50	37	69	14	14	0	3	70	3	7	17	3	0	33	63
Three or four levels (N = 30)	20	13	21	38	48	31	48	52	18	50	4	79	14	61	25	55	4	14	0	7	35	14	10	17	3	0	74	83

[a] The coding in the column headings of the auditory results is done in the same manner as explained in the text and detailed in the footnotes t Table III. All values are percentage of persons, not ears, possessing the trait of interest.
[b] The levels mentioned are those portrayed in Figure 8 and the explanation thereof. The 7 patients with symptoms of spinal cord damage only are included in the group with 2 sites of inferred lesion or less.
[c] One patient had no neurological symptoms on examination.

learned to interpret auditory test findings more adequately in relation to multiple sclerosis such tests may assist importantly in mapping the extent of a patient's sclerotic involvement

Another way of evaluating the relationship between site of neurological lesion and auditory behavior is to divide the 61 subjects on the basis of the number of neurological levels that were inferred to have been affected by sclerotic pathology A breakdown of the findings on this basis is shown in Table VIII Here comparison is made between the 30 subjects with signs attributed only to lesions at 1 or 2 of the levels in Fig. 8 and those with lesions at 3 or 4 of the levels Only the patient with no neurological symptoms at time of examination is omitted from Table VIII Analysis of Table VIII leads to the conclusion stated earlier namely widespread involvement within the CNS is more likely to be associated with auditory dysfunction than is spotty damage Only 30% of the less-involved group had significant threshold tone decay as compared with 52 % of the second group only 21 % of the less-involved subjects could not correctly handle speech in white noise as compared with 48 % of the more-involved group only 33 % of the first group had abnormally small 500 Hz MLDs as compared to 74 % of the second group etc Similar differences in incidence of abnormalities held true for most of the auditory tests

A sub-category of subjects of special interest is that group which exhibited the medial longitudinal fasciculus (MLF) syndrome because this syndrome is indicative of lesions in the midbrain There were 30 such persons The incidence of abnormal behavior for the entire sub-category was as follows 29 % could not correctly handle competing message tests, 40 % had poor discrimination for monosyllables in white noise 48 % had excess threshold tone decay (62 % of these bilaterally) 77 % yielded Type II or IV Békésy traces (43 % of these Type IV) 55 % gave decreased SISI scores 26 % demonstrated decruitment 40 % had reduced MLDs at 500 Hz, and 72 % had reduced MLDs for spondees

One third of these subjects had symptoms attributable to lesions only at the midbrain or higher in the CNS i e., at Levels 1 2, or 3 The remainder also had symptoms suggesting other CNS dysfunction in the low brainstem or cerebellum Although the overall incidence of auditory disorders was somewhat greater in the group with widespread lesion as would be expected those with only high CNS damage also performed poorly on many auditory tests 50 % had excess threshold tone decay 75 % gave Type II or IV Békésy traces, 63 % achieved low SISI scores, and 33 % had reduced MLDs for 500 Hz.

The important conclusions to be drawn from the foregoing discussion are that first this population as far as could be determined from detailed neurological data, was one characterized by lesions throughout the central nervous system and that second a significant proportion of the abnormal auditory behavior must be considered symptomatic of lesions central to the first order auditory neurons and their termini In other words, as is clear from the above discussion, clinically inferred lesions in the upper brainstem, midbrain and cortical areas of the CNS are as likely and in certain cases more likely to be paired with unusual auditory behavior than are those confined to the general area of the low brainstem Consequently it seems only reasonable to conclude that these aberrations in auditory behavior can be ascribed to multiple sclerotic lesions in the central auditory nervous system and that many of them are results of damage located central to the root of the VIIIth cranial nerve

III VESTIBULAR RESULTS IN RELATION TO NEUROLOGICAL FINDINGS

Forty four of the subjects in this study were given the formalized electronystagmographic examination described in Chapter II The distributions (percentages) of vestibular symptoms which emerged were classified in terms of the locations of the inferred sites of neurological lesion in Table IX and on the basis of the number of inferred sites in Table X

Table IX. *Incidence (percentage) of abnormal vestibular results[a] as a function of the location of inferred sites of neurological lesion[b] for 44 patients[c] with multiple sclerosis*

Inferred sites of lesion	Abnormal optokinetic tracking (A)	Abnormal pendulum tracking (B)	Positional nystagmus (C)	(Post-caloric) hyperexcitability (D)	Poor or reversed attenuation (E)	Unilateral paresis (F)	Abnormal slow tracking (G)	Dysrhythmia (H)	Spontaneous nystagmus (I)	Directional preponderance (J)	Lateral gaze imbalance (K)
Level 4 (N [illegible])	33	[illegible]	33	[illegible]	50	83	17	50	17	33	17
Levels 3 and 4 2, 3, and 4 (N = 9)	56	56	22	33	56	33	33	44	22	56	0
Levels 1 and or 2, and or 3 (N 7)[d]	71	57	71	29	43	57	[illegible]	43	43	14	14
Levels 1–4 (N 6)	67	67	17	50	50	50	100	33	33	50	33
Levels 1 and 4 2 and 4 1 and 3 1 .., and 4, 1 3, and 4 (N 11)[d]	73	64	36	64	55	9	45	55	55	36	27
Spinal cord (S) only (N 5)	40	20	100	60	20	0	0	20	60	20	20

The coding in the column headings of the vestibular results is done in the same manner as explained in the text. See Table VI and the footnotes for Table III

The levels mentioned are those portrayed in Fig. 8 and the explanation thereof. The last row contains values obtained from those patients with symptoms of spinal cord damage only at the time of neurological evaluation.

One patient had no neurological signs on examination.

One patient is common to these 2 groups

Even though the number of subjects in each category of Table IX is small, the following general trends may be observed therein. The 6 individuals with involvement limited to Level 4 (brainstem) showed high incidences of post caloric hyperexcitability (83 %), unilateral paresis (83) and dysrhythmia (50) The 9 subjects having brainstem symptoms (Area 4) plus midbrain involvements (Level 3 or Levels 2 and 3) had approximately 50 incidence of all symptoms except positional nystagmus (22), abnormal slow tracking (33 %), post-caloric hyper excitability (33), unilateral paresis (33 %), spontaneous nystagmus (22), and lateral gaze imbalance (0) A high proportion of the 7 persons showing cortico-optic (Level 1) plus midbrain (Levels 2 or 3) neurological symptomatology exhibited abnormal optokinetic tracking (71) and positional nystagmus (71), with few showing lateral gaze imbalance directional preponderance, abnormal slow tracking, or hyperexcitability Other vestibular symptomatology (see Table IX) was noted in about half the subjects. The 6 persons with inferred lesions in all 4 areas exhibited abnormal slow tracking, two-thirds of them yielded abnormal optokinetic tracking and abnormal pendulum tracking; half showed hyperexcitability poor attenuation, unilateral paresis, and directional preponderance while a third or less showed unsolicited nystagmus, lateral gaze imbalance, or dysrhythmia. Another group of subjects (11), with apparently spotty neurological involvement, had a high percentage of abnormal optokinetic tracking (73 %) abnormal pendulum tracking (64 %), and post-caloric hyperexcitability (64 %) combined with very infrequent unilateral paresis (9 %)

The 5 persons whose only inferred lesions were in the spinal cord yielded little evidence of vestibular dysfunction Notice in Table IX that incidence was 20% or less in 7 of the 11 cate

learned to interpret auditory test findings more adequately in relation to multiple sclerosis, such tests may assist importantly in mapping the extent of a patient's sclerotic involvement

Another way of evaluating the relationship between site of neurological lesion and auditory behavior is to divide the 61 subjects on the basis of the number of neurological levels that were inferred to have been affected by sclerotic pathology A breakdown of the findings on this basis is shown in Table VIII Here comparison is made between the 30 subjects with signs attributed only to lesions at 1 or 2 of the levels in Fig 8 and those with lesions at 3 or 4 of the levels Only the patient with no neurological symptoms at time of examination is omitted from Table VIII Analysis of Table VIII leads to the conclusion stated earlier namely widespread involvement within the CNS is more likely to be associated with auditory dysfunction than is spotty damage Only 30% of the less-involved group had significant threshold tone decay as compared with 52% of the second group, only 21% of the less-involved subjects could not correctly handle speech in white noise as compared with 48% of the more-involved group, only 33% of the first group had abnormally small 500 Hz MLDs as compared to 74% of the second group etc Similar differences in incidence of abnormalities held true for most of the auditory tests

A sub-category of subjects of special interest is that group which exhibited the medial longitudinal fasciculus (MLF) syndrome because this syndrome is indicative of lesions in the midbrain There were 30 such persons The incidence of abnormal behavior for the entire sub-category was as follows 29% could not correctly handle competing message tests 40% had poor discrimination for monosyllables in white noise 48% had excess threshold tone decay (62% of these bilaterally) 77% yielded Type II or IV Békésy traces (43% of these Type IV), 55% gave decreased SISI scores 26% demonstrated decruitment, 40% had reduced MLDs at 500 Hz, and 72% had reduced MLDs for spondees

One third of these subjects had symptoms attributable to lesions only at the midbrain or higher in the CNS i e., at Levels 1 2, or 3 The remainder also had symptoms suggesting other CNS dysfunction in the low brainstem or cerebellum. Although the overall incidence of auditory disorders was somewhat greater in the group with widespread lesion as would be expected those with only high CNS damage also performed poorly on many auditory tests 50% had excess threshold tone decay 75% gave Type II or IV Békésy traces, 63% achieved low SISI scores, and 33% had reduced MLDs for 500 Hz.

The important conclusions to be drawn from the foregoing discussion are that first this population as far as could be determined from detailed neurological data was one characterized by lesions throughout the central nervous system and that second a significant proportion of the abnormal auditory behavior must be considered symptomatic of lesions central to the first order auditory neurons and their termini In other words, as is clear from the above discussion, clinically inferred lesions in the upper brainstem, midbrain, and cortical areas of the CNS are as likely and in certain cases more likely to be paired with unusual auditory behavior than are those confined to the general area of the low brainstem Consequently it seems only reasonable to conclude that these aberrations in auditory behavior can be ascribed to multiple sclerotic lesions in the central auditory nervous system, and that many of them are results of damage located central to the root of the VIIIth cranial nerve

III VESTIBULAR RESULTS IN RELATION TO NEUROLOGICAL FINDINGS

Forty-four of the subjects in this study were given the formalized electronystagmographic examination described in Chapter II The distributions (percentages) of vestibular symptoms which emerged were classified in terms of the locations of the inferred sites of neurological lesion in Table IX and on the basis of the number of inferred sites in Table X

there are particular relationships of interest to the reader which are not discussed in the text, he will find references to Tables IV V VII, and VIII useful.

A. Threshold sensitivity for pure tones

The pure tone threshold levels exhibited by the 61 subjects were sufficiently good to allow the conclusion that substantial hearing loss was not a hallmark of the group. Neither however can the results be classified as free from unusual characteristics Depression in sensitivity at 1 or more frequencies ranged from mild (30 or 35 dB HL) to severe (over 65 dB HL) in 64 of the 122 ears involved. This means that in only 58 instances was sensitivity 25 dB HL or better across the entire frequency range. These proportions are not typical, particularly when one recalls that poor thresholds often occurred at unusual frequencies. Consider also the audiometric patterns that the group exhibited. It is particularly noteworthy that the arched pattern, uncommon in the hearing impaired population, except possibly in the very elderly population (Goetzinger et al 1961), appeared 17 times The 61 multiple sclerotic patients studied here were not an elderly group Also predominantly low frequency defects as compared to those in the mid-frequencies appeared 8 additional times in other audiometric contours Furthermore recall that in the group of ears with normal thresholds, 11 had arched contours and 7 had rising configurations. Thus, one comes to the conclusion that many of our 61 subjects exhibited subtle but real disturbances in sensitivity for pure tones in consequence of their multiple sclerosis and that one of the most distinctive (but not necessarily the most important) symptoms of such disturbance was the arched audiometric pattern

It is intriguing to speculate on the significance of the arched contour This pattern is characterized by better hearing in the mid-frequencies, (often within the range of normal sensitivity) than in the low or high frequencies. Given the apparent orderliness of the auditory system tonotopically such a configuration is difficult to envision as resulting from a localized and specific invasion of the VIIIth nerve trunk or of some deeper portion of this tonotopic system. Granted, such a geographically unique invasion might occur rarely but its repeated appearance would require an astonishing geographic predilection for the sclerotic invasion to occupy uniquely restricted areas. This possibility is most unlikely A more reasonable explanation would seem to be that a variety of lesions beyond the VIIIth nerve trunk disrupt to some degree the mechanisms involved in transmitting frequency information within the central nervous system. One can at present only guess at what these mechanisms are but they must exist. It is unlikely that the auditory nervous system furnishes only a series of replicative transmission paths through the various levels from cochlea to cortex. Moreover at least peripherally the volley mechanism probably is predominant at low frequencies, with the place mechanism increasing its predominance as frequency increases. Such a dual system must depend upon dissimilar central response to incoming volley and to incoming place information, with the consequent prospect that central lesions affecting transmissional pathways and neuronal networks may disrupt perception of some frequencies more than others. Among other things, it is reasonable to presume that such disruptions could include both efferent and afferent functions, as well as the interactions between them [1] In point of fact, 1 in every 3

[1] Gravendeel (1958), although not specifically discussing multiple sclerosis, postulates mechanism which, if present, could account for the low frequency defect in the arched audiogram. He presumes that low frequency hearing loss can be caused by hyperactivity of the efferent system He suggests that lesions within the central auditory system can produce such hyperactivity He reports obtaining the arched configuration from patients with disease processes and/or surgical intervention in the fourth ventricle, the mesencephalon and the lateral lemniscus It is Gravendeel's contention that the low frequency component of hearing loss in these cases was due to a resultant hyperactive efferent system and that the high frequency component, which was occasionally transitory was due to dysfunction of the afferent fibers in the brainstem and/or higher CNS Along this line it is of interest that slight low frequency hearing defects have been reported for poliomyelitis (Batton & McConnell, 1958 McConnell & Batton, 1962) Other authors have proposed that low

Table X *Incidence (percentage) of abnormal vestibular results[a] as a function of the number of inferred sites of neurological lesion[b] for 44 patients[c] with multiple sclerosis*

Number of inferred sites of lesion	Abnormal optokinetic tracking (A)	Abnormal pendulum tracking (B)	Positional nystagmus (C)	(Post-caloric) hyperexcitability (D)	Poor or reversed attenuation (E)	Unilateral paresis (F)	Abnormal slow tracking (G)	Dysrhythmia (H)	Spontaneous nystagmus (I)	Directional preponderance (J)	Lateral gaze imbalance (K)
Two levels or less ($N=22$)	45	45	59	64	45	27	18	45	50	77	18
Three or four levels ($N=21$)	71	62	4	38	43	43	62	38	24	48	19

[a] The coding in the column headings of the vestibular results is done in the same manner as explained in the text. See Table VI and the footnotes for Table III

[b] The levels mentioned are those portrayed in Fig. 8 and explanation thereof The 5 patients with symptoms of spinal cord damage only are included in the group with 2 sites of inferred lesion or less.

[c] One patient had no neurological symptoms on examination.

gories of vestibular abnormality The prominent exceptions to such behavior were the 3 persons who exhibited post-caloric hyperexcitability the 3 who possessed spontaneous nystagmus, and the 5 persons (the entire group) who had positional nystagmus Since only 5 subjects with spinal multiple sclerosis were given the vestibular evaluation it is difficult to determine whether the abnormalities detected were results of CNS lesion not discovered on neurological evaluation of concomitant pathology or simply of chance occurrences However it does not seem highly probable that the observation of positional nystagmus in all 5 subjects with only spinal symptoms could be chance alone

When the data are considered in terms of the number of areas affected (Table X) positional nystagmus, post-caloric hyperexcitability and spontaneous nystagmus were more prevalent in the group (N = 22) having involvement at 1 or 2 levels than in the group (N = 21) with 3 or 4 levels affected The reverse was true for abnormal optokinetic tracking, abnormal pendulum tracking, unilateral paresis and abnormal slow tracking. The 2 groups were essentially equivalent in terms of the remaining vestibular symptoms.

It is clear from these results that abnormalities revealed by the ENG evaluation were not confined to those subjects with symptoms referrable to lesions in Level 4 the area within which the vestibular branch of the VIIIth nerve terminates in the vestibular nuclei Conversely except for abnormal slow tracking in the 6 cases where all 4 areas were involved and the 5 spinal cord subjects with positional nystagmus no vestibular symptom was always associated with a particular configuration of inferred neurological lesion As with the auditory results, this outcome is not startling in view of the diversity of pathology suffered by multiple sclerotic patients Finally and this generalization is not apparent from the tables that are given the ENG results did not appear to correlate with the auditory results in a meaningful manner This latter outcome may be the result of the limited sample of data currently available Hopefully further research will clarify this situation

IV IMPLICATIONS OF SPECIFIC AUDITORY FINDINGS

The ensuing discussion concerns itself with how the results of the various auditory tests administered to these subjects can be interpreted in terms of the causes of abnormality and what the implications of such analysis may be If

competing message test is produced primarily by temporal lobe dysfunction and multiple sclerosis has a predilection for sites lower within the CNS therefore high level auditory symptoms would not be expected too often.

Aberrant behavior appeared more commonly hen discrimination was measured against a background of white noise, falling below 60% for 28 of the ears through which the test was administered. Moreover discrimination in quiet was also reduced in only 8 of these 28 instances. The remaining 20 cases represent instances in which breakdown was not revealed by any of the traditional measures already discussed When one takes into account the concomitant results for the several tonal tests discussed ear lier it would appear that these results bespeak in most cases brainstem lesions that did not produce noteworthy loss in either hearing sensitivity or speech discrimination in quiet Of course, there are the cases alluded to before in which difficult speech tests demonstrated break down in the absence of abnormality on tonal tests, and it is reasonable to assume that these findings result from higher level CNS damage. Of particular interest is the fact that reduced performance on competing message tasks usually heralded similar or greater difficulty on the speech in white noise test Sinha (1959) has suggested that temporal lobe disease can affect the understanding of speech presented against a background of white noise The opposite of this situation is not invariably true, i e breakdown on speech in white noise tasks does not invariably presage trouble when competing messages are presented to the ears The obvious conclusion is that the speech in white noise test is sensitive to the presence of damage n more parts of the auditory system than is the competing message test This conclusion is supported by the fact that although breakdown in discrimination for speech in white noise was most common in those subjects with neurologically placed lesions at Levels 1–4 (63 abnormal), it was also common in persons whose lesions were thought to be limited to regions superior to Level 4 (40% abnormal). As with most tests, the more wide spread the symptoms of CNS lesion, the higher the incidence of abnormality

Breakdown on the filtered speech test oc curred 9 times out of 72 presentations, and then predominantly when discrimination in quiet was excellent. Only half the time was filtered speech reception abnormal when competing speech scores were low but speech in white noise scores were usually abnormal if filtered speech produced difficulty This difficulty was almost always unilateral, i.e., if scores were reduced, the decrease in performance was almost always monaural In addition aberrations for filtered speech tended to cluster in relation to the results on the other tests in such a manner that, in the authors opinion this test as presented here almost exclusively revealed breakdown via 1 ear that is, it almost never provided information suggesting damage to binaural correlative mechanisms Finally breakdown on this test, when it did occur was much more common in persons whose lesions were inferred to be in Levels 1–3 than at Level 4 Thus, the filtered speech test used in this study probably was much more sensitive to high level CNS lesions than to low level ones if some of the patients possessed le sions of the binaural correlative mechanisms within the CNS, this test did not emerge as sensitive to such lesions.

D **Threshold tone decay**

The traditional interpretation of threshold tone decay is that excess amounts of decay (more than 30 dB) are indicative of retrocochlear involvement. This degree of abnormality was apparent via 38 of the 120 ears tested for such behavior This proportion is much higher than would appear in an ordinary population with hearing as good as the 61 subjects discussed here (Wille ford, 1960). Hence, one may conclude that in most of the instances where excess tone decay appeared, the test was revealing an aberration of function brought about by sclerotic lesions

The distribution of results gives some clue to the probable loci of lesions. Of the 38 ears with threshold tone decay exceeding 30 dB, 23

persons exhibiting the arched pattern had neurological signs suggesting midbrain or higher CNS lesions. Almost all of these had bilateral arched configurations and also yielded abnormal responses on most tests of special interest was the fact that 67 % had excess tone decay 33 % bilaterally

Remembering that central auditory lesions usually have little influence on pure tone thresholds, one may reason that the cases among these subjects in whom the symptoms just discussed were present probably possessed appreciable involvement within the auditory CNS Furthermore the fact that aberrations such as the arched contour were monaural in many instances may be taken as evidence confirming the view that for a substantial distance the CNS maintains 2 functionally independent (although closely interconnected) auditory pathways, each serving 1 ear Finally since pure tone sensitivity is relatively unaffected by central lesions and pathologies (Bunch, 1928 Bocca & Calearo 1963 Stein, 1963 Jerger 1964) unless the involvement is bilateral and extensive (Jerger 1970) the fact that a patient did not show elevated thresholds to pure tones does not rule out the possibility that he possessed central auditory pathology that manifested itself in unusual threshold configurations and/or in other ways when faced with more difficult auditory tasks.

B Threshold sensitivity for speech

Speech reception thresholds were poorer than 25 dB for only 6 ears. Tests of these same ears yielded pure tone averages for 500–2 000 Hz of similar severity This proportion of loss is slightly higher than a random selection of adults in the same age range would be expected to yield However the overall pattern of findings suggests that peripheral hearing loss was probably present for half these ears Consequently since (CNS) lesions were clearly present in the subjects under study the lack of widespread insensitivity for spondee materials suggests that responsiveness to this type of speech can remain adequate despite appreciable involvement of the auditory pathways and centers. Of course it would not be surprising to find specific instances in which the situation is different.

C. Discrimination for speech

Perception of monosyllables in quiet surroundings was for the most part very good. For only 9 ears (7 individuals) was the discrimination score poorer than 90 %. In 4 of these cases, an appreciable hearing loss was apparent for 500-2 000 Hz pure tones and in 3 of them, a loss was present for spondees. Since all cases of reduced discrimination for speech in quiet were not thus accounted for it was concluded that reduced discrimination occasionally indicated a breakdown in function that was not already revealed by sensitivity measurements Six of the 7 individuals involved had neurological symptoms thought attributable to Level 4 and 3 of these 6 had lesions at all 4 levels. Thus, breakdown of accurate speech discrimination was usually accompanied by damage in the region of the auditory nuclei and trapezoid body and/or was widespread in the CNS However there are other individuals in the sample with similar loci of inferred lesion whose discrimination was good

The situation proved to be slightly different for the competing speech test Twelve individuals obtained lower than normal scores on this test Five of these persons also yielded reduced scores in quiet for 1 or both ears Interestingly in only 1 ear among those ears (7) through which reduced discrimination scores in quiet were obtained was the score on the competing message task dramatically reduced re the score in quiet Of the other 8 ears, however 6 had impaired performance for competing speech through 1 ear and 1 case via both ears even though discrimination in quiet via both ears was excellent The relatively few instances of breakdown on this test are understandable since difficulty on the

frequency hearing losses in multiple sclerosis are due to lesions manifesting themselves as conductive hearing loss (Simpkins, 1961) or due to damage to the VIIIth nerve (Sopek & Sipowicz, 1969) These possibilities do not seem to us as likely

hroughout the 3 minutes that were allotted to a ingle tracing. Thus, it may well be that the damage inflicted on central auditory structures by lemyelination often shows itself as modest, ongoing adaptation of threshold responsiveness to continuous tones. If so, the resultant tracings were classified as Type II because the total extent of this adaptation did not exceed the shift re the interrupted tracing (20 dB) specified as the maximum for a Type II result.

In this regard, it is pertinent to note that there were 17 instances of Type IV tracings, but that these, too, were usually characterized by a continuing slow drift. Such Type IV tracings were analogous, except for their more rapid drift, to the Type II tracings mentioned above. Hence, it may well be artificial in the present instance to make a distinction between Type II and Type IV results. Both sets probably represent similar symptomatology differing in degree rather than kind. From this point of view both may be attributed to disruption of central processes. Moreover the critical feature is that both are clearly unlike the rapid, disruptive adaptation so often caused by VIIIth nerve lesions which reveals itself in the Type III Békésy tracing.

The most startling fact in the Békésy data is that Type III tracings emerged only 2 times out of 115 series of tests and these 2 examples of extreme adaptation were obtained via the 2 ears of 1 subject. This subject also had extreme, bilateral, threshold tone decay. The rarity of this symptomatology in the present series of subjects is unexpected, but it supports the previously expressed view that serious involvement of the VIIIth nerve trunk probably was not a frequent manifestation of multiple sclerosis in this population.

The relationships observed between the Békésy tracings and excess tone decay warrant further comment. Thirteen of the 14 persons with severe bilateral tone decay were also given Békésy tests. Considered by ears, there were 11 Type IV 10 Type II 3 Type I and 2 Type III tracings. One sees here a combination of results which is clinically unique, namely a consistent linkage of excess tone decay and either Type IV or Type II Békésy traces. This relation appears to be another clue that the excess adaptation exhibited by many patients with bilateral tone decay was due to lesions deep to the auditory nerve trunks. A further point of interest is that 15 of the 17 instances of Type IV tracing involved ears through which excess tone decay was also recorded. This is one of the few circumstances within the findings in which nearly all aberrant responses on 1 test were matched by aberrant responses on another. Clearly therefore, the Type IV tracings encountered here seemed to depend on a disruption of central function which also manifested itself through excess tonal adaptation.

F Short increment sensitivity

High SISI scores were obtained via 14 ears when the test was administered at 20 dB SL. These responses were found predominantly in cases with some impairment in pure tone sensitivity Type II Békésy tracings, and modest tone decay. In view of this combination of symptoms, it is likely that at least for the most part, these high SISI scores were indications of occasional end-organ involvement that was not related to the patient's multiple sclerosis. There were a few cases where high SISI scores appeared in combination with conventional retrocochlear findings, but the sample size here is so small that speculation about this circumstance is unwarranted.

Conversely there were 52 instances where short increment sensitivity was substantially poorer than normal. These were subjects who either could not detect 2.5 dB increments at 20 dB SL and/or at 85 dB HL or else who scored 55% or less at [illegible] dB HL for at least 1 test frequency. This concentration of atypical responses is very high and probably should be interpreted as resulting from multiple sclerosis. Curiously the incidence of decreased SISI scores clusters around 50–60 in almost any group of subjects chosen on the basis of their neurological symptoms. This finding suggests that extensive CNS lesions affecting the auditory system, regardless of the level at which they occur can produce the

had normal threshold sensitivity at the frequency where maximum decay was elicited and none of the other 15 had loss greater than 40 dB at these frequencies Moreover 31 of the 38 ears in question did not exhibit a deficit exceeding 35 dB at *any* frequency The lack of reduced threshold sensitivity for these 38 ears is unlike the typical finding with cases of VIIIth nerve tumor where excess tone decay is accompanied by definite hearing loss [1] One is therefore led to the opinion that in the instances under consideration, the excess tone decay was caused by lesions more centrally located than the VIIIth nerve trunk.

This view is supported by the fact that 14 of the 61 subjects had bilateral threshold tone decay and there were only 10 instances of unilateral threshold tone decay The probability of both VIIIth nerve trunks being affected in 1 out of every 4 of the subjects in this sample or of at least 1 VIIIth nerve trunk being affected in 2 out of every 5 is unlikely Even more telling is the fact that although 12 of these individuals (20 ears) had complete threshold tone decay at some frequency 8 of them bilaterally they had good hearing in other respects These cases did not show the gross symptoms of breakdown that usually accompany malfunction of the auditory nerve It should be especially noted that their discrimination for speech in quiet was excellent 34 of the 38 ears via which extreme threshold adaptation was elicited had speech discrimination scores of 90 or better Remember that in patients with VIIIth nerve tumor sharply impaired discrimination for speech in quiet is a common symptom

Although the case for claiming that the excess tone decay encountered in this study is due to lesions above the VIIIth nerve is especially strong for the subjects with bilateral decay the same conclusion emerges from the data on unilateral tone decay Here, too the concomitant findings were good hearing for pure tones and for speech Interestingly the cases exhibiting unilateral decay showed less severe adaptation than those with bilateral decay only 3 of 10 unilaterals had complete tone decay but 9 of 14 bilaterals had complete tone decay 8 of them bilaterally In addition, the unilateral cases usually had Type I or II Békésy traces (7 of 10) while half the bilateral cases (13 of 26) had Type III or IV traces. Possible implications of these last findings are that different loci of sclerotic lesion are indicated by these two patterns of response and that the cases of bilateral decay may often result from manifestations of more widespread CNS lesion.

[1] Another facet of the threshold performance of these subjects is that their threshold configurations were quite atypical of VIIIth nerve lesion e.g., 25 of the 38 had flat, arched, rising, or notched configurations.

E. Békésy threshold tracing

Békésy threshold tracings were obtained via 115 ears. Thirty-four of the result were Type I tracings, while 62 were Type II Type III tracings occurred only twice and 17 were Type IV In view of the fact that the population in question is characterized by CNS lesions, this distribution of findings is most provocative One point of interest is the relatively small proportion of patients who yielded exclusively Type I records A full 70 % of the tracings were abnormal in some way One must assume that the majority of these abnormal tracings were manifestations of multiple sclerosis, since a proportion of this magnitude is in no way typical of the population at large Equally provocative is the fact that more than 50 of all sets of tests yielded some Type II tracings This fraction too is out of line with the population at large Moreover Type II tracings are traditionally interpreted to indicate cochlear lesions, and the group of subjects being discussed here is one in which cochlear lesions were rare at most and CNS involvement was the rule The most reasonable interpretation of this paradox would seem to be that Type II tracings can result from central auditory lesions, but that this situation has gone unnoticed because patients with such lesions are in the minority in ordinary clinical situations Here incidentally it is pertinent to remind the reader that many of the Type II records in question were unusual in that they revealed slow ongoing adaptation

ence As a final comment, it is interesting to observe that this imbalance usually was not concomitant with the type of breakdown in processing of binaural information revealed by the filtered speech test.

I. Masking level differences

Twenty-three of the 47 persons so tested had MLDs at 500 Hz that were abnormally small (7 dB or less) and the same was true of 30 out the 42 persons given the test with spondees (5 dB or less). Thus, unusual MLD performance was very common. Particularly noteworthy in this regard is the fact that almost all of the persons yielding small MLDs had bilaterally normal thresholds for 500 Hz and for spondees. For this reason, it seems safe to assume that 2 potential sources of decreased release from masking, namely end-organ pathology and VIIIth nerve damage, were absent in a preponderance of these subjects. This interpretation leads to the further assumption that the reduced MLDs exhibited by this population were the result of lesions within the central nervous system.

One might presume that the proper functioning of cross-correlational mechanisms at the medullo-pontine level are particularly critical in achieving normal MLDs, e.g. that the initial separation of signal from background occurs in the centers where binaural stimuli are first mixed. However when one considers the results in relation to the inferred sites of neurological lesion in our population, one finds that the incidence of reduced MLDs was as great in those cases where the brainstem was not involved as in those cases where only the brainstem was involved or where the midbrain was affected along with the brainstem. Thus, it would appear that MLD performance is sensitive to pathology throughout much of the central auditory nervous system. Moreover the fact that MLD tests yielded such a high proportion of abnormal responses suggests that these tests are quite sensitive to the lesions which multiple sclerosis produces. Spondee materials appear to be particularly good in this regard.

One must remember that normal release from masking (large MLDs) can occur only if cross-correlational mechanisms are interrelating binaural stimulus trains properly. As already mentioned it appears from the present findings that the critical cross-correlational processes are not limited to the brainstem. One may speculate that a possible source of disruption in cross-correlational function may be a change in neural transmission (McDonald & Sears, 1970) engendered by partial or complete demyelination within the auditory tracts which disrupts the synchrony and completeness of the nerve impulse trains reaching correlational centers at more than 1 level in the central auditory nervous system.

V FINAL COMMENT

The foregoing discussion is incomplete. There is still a tremendous amount to be learned about the auditory responses of multiple sclerotic patients, about the change in these responses over time, and about the relationship of these responses to the lesions that produce them. Therefore, the remarks in this chapter must be considered merely as early thoughts in the search for this knowledge. Nonetheless, 2 features of the data stand out as deserving mention.

First, the great majority of these multiple sclerotic patients in this sample exhibited aberrant auditory behavior. These manifestations of auditory abnormality were usually subtle. Such tests as those determining sensitivity for pure tones or spondaic words or those probing speech discrimination in quiet settings were generally performed in a normal or only slightly depressed fashion by this group. However more difficult speech and tonal tests often revealed unusual auditory behavior. The information at hand does not yet allow one to draw generalizations indicating the interpretative significance of clusterings of audiological findings. However interrelations exist and further study of the auditory behavior of multiple sclerotic patients coupled with good neurological data (and post mortem findings when available) should lead to such generalizations. If they do so, the use of

abnormal SISI scores It is noteworthy however that a substantial fraction of such responses occurred for ears evidencing excess tone decay and/or Type II or Type IV Békésy tracings. Thus one may speculate that the same central lesions which produced the latter types of response often brought about desensitization to short increments of intensity

G Loudness balance

Twenty two of the 59 subjects who were given the ABLB test evidenced atypical loudness relations In 8 instances, recruitment was present and here there was also a tendency for tone decay to be modest, Békésy tracings to be Type II and SISI scores to be high. Thus, some of the recruitment responses observed here are probably attributable to conditions other than multiple sclerosis. In some ears, though recruitment was elicited in combination with otherwise predominantly retrocochlear signs There is, as yet an insufficient group of subjects of this sort to make comment meaningful

The remaining 14 persons with abnormal ABLB responses exhibited decruitment or no recruitment in ears with hearing loss Excess tone decay Type IV Békésy tracings, and desensitization to short increments of intensity appeared in over half of these ears. Such clustering leads to the speculation that these several symptoms may have been due to the same sclerotic lesions. If so and since it is reasonable to presume from neurological evaluation of these subjects and from other auditory signs that many of the lesions were in the brainstem and mid brain decruitment would also at times be the product of such involvement Such a situation would not preclude its appearing in other individuals because of cortical lesions (Davis & Goodman 1966) or VIIIth nerve damage (Tillman 1969)

H Median plane localization

Forty-eight subjects required equally intense tones in the 2 ears to achieve a median plane localization and 12 others either could not experience a midline image or else did so only when unequal stimulation was present at the 2 ears. The latter 12 individuals may be judged to have shown aberrant responses in the sense that both normal hearers and sensorineural loss cases usually achieve localization with approximately equal intensities at the 2 ears. Such aberrance has been found in consequence of VIIIth nerve damage but also occurs when the damage is deeper (Jerger 1960*b*) It is interesting to observe that among the present group of subjects, abnormal localization occurred only 3 times in conjunction with decruitment but it appeared 9 times in instances where large SISI increments were not heard 5 times when there was excess tone decay and 8 times when MLDs were abnormally small These relations lead to the speculation that this aberrance in response to the localizational task is indicative of lesions that are dissimilar to those inducing decruitment. However this is a prospect that can be clarified only through substantial future exploration.

An outstanding feature of the present findings is that of the 12 multiple sclerotic subjects yielding abnormal median plane localization results, only 5 had difficulties in performing the localization task Thus, only a twelfth of the cases with multiple sclerosis suffered from this problem It has long been known that patients with brainstem lesions often find this task tremendously taxing in that they have great difficulty either perceiving a localizable image or in getting this image to shift Since neurological results suggest that brainstem lesions were common in this group the limited incidence of gross breakdown in lateralizational ability can be interpreted as indicating that multiple sclerosis often did not produce lesions which totally disrupted intracranial localizational ability although in some cases its lesions appeared to cause the more subtle imbalance in the central processing of interaural signals that necessitates use of interaural intensity differences to achieve a centered image However in some cases the damage was of such nature as to disrupt the mechanism underlying the lateralization experi-

ence As a final comment, it is interesting to observe that this imbalance usually was not concomitant with the type of breakdown in processing of binaural information revealed by the filtered speech test.

I. Masking level differences

Twenty-three of the 47 persons so tested had MLDs at 500 Hz that were abnormally small (7 dB or less) and the same was true of 30 out of the 42 persons given the test with spondees (5 dB or less). Thus, unusual MLD performance was very common. Particularly noteworthy in this regard is the fact that almost all of the persons yielding small MLDs had bilaterally normal thresholds for 500 Hz and for spondees. For this reason, it seems safe to assume that 2 potential sources of decreased release from masking, namely end-organ pathology and VIIIth nerve damage, were absent in a preponderance of these subjects. This interpretation leads to the further assumption that the reduced MLDs exhibited by this population were the result of lesions within the central nervous system.

One might presume that the proper functioning of cross-correlational mechanisms at the medullo-pontine level are particularly critical in achieving normal MLDs, e.g. that the initial separation of signal from background occurs in the centers where binaural stimuli are first mixed. However, when one considers the results in relation to the inferred sites of neurological lesion in our population, one finds that the incidence of reduced MLDs was as great in those cases where the brainstem was not involved as in those cases where only the brainstem was involved or where the midbrain was affected along with the brainstem. Thus, it would appear that MLD performance is sensitive to pathology throughout much of the central auditory nervous system. Moreover, the fact that MLD tests yielded such a high proportion of abnormal responses suggests that these tests are quite sensitive to the lesions which multiple sclerosis produces. Spondee materials appear to be particularly good in this regard.

One must remember that normal release from masking (large MLDs) can occur only if cross-correlational mechanisms are interrelating binaural stimulus trains properly. As already mentioned, it appears from the present findings that the critical cross-correlational processes are not limited to the brainstem. One may speculate that a possible source of disruption in cross-correlational function may be a change in neural transmission (McDonald & Sears, 1970) engendered by partial or complete demyelination within the auditory tracts which disrupts the synchrony and completeness of the nerve impulse trains reaching correlational centers at more than 1 level in the central auditory nervous system.

V. FINAL COMMENT

The foregoing discussion is incomplete. There is still a tremendous amount to be learned about the auditory responses of multiple sclerotic patients, about the change in these responses over time, and about the relationship of these responses to the lesions that produce them. Therefore, the remarks in this chapter must be considered merely as early thoughts in the search for this knowledge. Nonetheless, 2 features of the data stand out as deserving mention.

First, the great majority of these multiple sclerotic patients in this sample exhibited aberrant auditory behavior. These manifestations of auditory abnormality were usually subtle. Such tests as those determining sensitivity for pure tones or spondaic words or those probing speech discrimination in quiet settings were generally performed in a normal or only slightly depressed fashion by this group. However, more difficult speech and tonal tests often revealed unusual auditory behavior. The information at hand does not yet allow one to draw generalizations indicating the interpretative significance of clusterings of audiological findings. However, interrelations exist and further study of the auditory behavior of multiple sclerotic patients coupled with good neurological data (and post mortem findings when available) should lead to such generalizations. If they do so, the use of

audiological procedures will eventually come to have unique value in assisting in the identification of sclerotic pathology in the living person

Second, remember that involvement of the VIIIth nerve trunk appeared to be relatively rare in the group of patients with multiple sclerosis under study Most of the distinctive auditory symptomatology these individuals exhibited is consequently attributable to disturbances within the central auditory nervous system Much of this symptomatology mimicked responses traditionally associated with inner ear lesions although some mimicked behavior induced by VIIIth nerve pathology Clearly it becomes necessary to rethink the diagnostic significance of the entire array of auditory tests when CNS lesions such as multiple sclerosis are a possibility This does not mean that test findings do not have the conventional meanings when encountered in the presence of peripheral auditory diseases and disorders It does mean that the same findings can have new meanings when CNS lesions are present. Here, too is an area where the further study of the auditory behavior of multiple sclerotic subjects coupled with good supporting data should prove most productive.

Zusammenfassung

Dieser Anhang präsentiert auditorische vestibuläre und neurologische Daten, die von 61 Personen stammen, die an multipler Sklerose erkrankt sind. Diese Menschen wurden weitgehenden Testen auf den oben genannten Gebieten ausgesetzt, um dadurch mehr über die Funktion des menschlichen zentralen auditorischen und vestibulären Nervensystems zu lernen. Auditorische und vestibuläre Erkenntnisse wurden im verhältnis zur neurologischen Mitwirkung des unteren Hirnstammes, des oberen Hirnstammes, des Mittelhirnes und der Rinde analysiert, wie die neurologischen Untersuchungen ergaben. Die Folgerungen, die man aus den Testergebnissen ziehen konnte, wurden mit den Tatsachen vor Augen, dass multiple Sklerose eine Krankheit des zentralen Nervensystems ist, beachtet.

Die neurologischen Bewertungen enthielten Untersuchungen des Krankheitswerdegangs, der klinischen, laboratorischen und medizinischen Berichte die von allen Kranken zur Verfügung stand und genaue klinische, neurologische von dem Neurologen unseres Projektes unternommene Untersuchungen. Mit Hilfe solcher und, wenn nötig, anderer besonderer Methoden, wurde die beschädigte Lage von dem Neurologen unseres Projektes in Form von vier allgemeinen Stufen des zentralen Nervensystems angegeben. Diese eingeteilten Stufen der Beschädigung wurden bei der Analyse der auditorischen und vestibulären Daten in Betracht gezogen.

Die Serie der auditorischen Tests bestand aus den üblichen Prüfungen der Ton- und Sprachschwelle, aus einer Fähigkeitsprüfung einsilbige Wörter zu unterscheiden so-wie aus einer Reihe von besonderen Ton- und Sprachprüfungen.

Die 6 besonderen Tonproben, die zur Anwendung gekommen sind, umfassten Prüfungen der Anpassung, der Lautheitsfunktion und kurzer Zunahmeempfindlichkeit sowie drei Untersuchungen der binauralen auditorischen Funktion.

Die vier Sprachuntersuchungen enthielten die Proben des Unterscheidungsvermögens von einsilbigen Wörtern bei ipsilateralem Weisslärm, im Gegensatz zu kontralateraler Wettbewerbssprache, in den verschiedenen filterten Arten und unter verschiedenen binaural maskierenden Situationen.

Die vestibulären Bewertungen umfassten vier hauptsächliche Arbeitsmethoden nämlich eine Gruppe von Tests, die sich mit visuellen induzierten Augenbewegungen einer Kontrolle des Spontannystagmus, der Suche nach dem Lagenystagmus und einer Überprüfung der Erwiderung zur Kalorien-erregung befasste. Alle Bewertungen wurden mit Hilfe von Elektronystagmographie ausgeführt.

Sowohl *einzeln* als auch in dem Umfang in dem sie zu einem Ergebnis modell gehörten wurden die Resultate betrachtet. Die neurologischen Bewertungen der 61 Versuchspersonen enthüllten, im allgemeinen, Symptome, die multiple Stufen — Schäden vom zentralen Nervensystem, insbesondere vom Mittelhirn und Hirnstamm vermuten lassen. Auditorische Bewertungen bewiesen eine ausgezeichnete Mannigfaltigkeit auditorischer Aberrationen, die meistens durch Untersuchungen, die zum anhaltenden Anreiz eine Reaktion erforderte, die Sprachunterscheidung in der abnormalen Bedingungen sowie die binauralen maskierenden Proben, bestimmt wurden. Auch die vestibulären Bewertungen zeigten eine gleichartige Veränderung in den Ergebnissen, die bemerkenswert waren. Unter den gewöhnlichsten Erkenntnissen waren abnormale visuell induzierte Augenbewegungen, Lagenystagmus und Übererregbarkeit als Antwort auf den Kalorien-anreiz.

audiological procedures will eventually come to have unique value in assisting in the identification of sclerotic pathology in the living person

Second remember that involvement of the VIIIth nerve trunk appeared to be relatively rare in the group of patients with multiple sclerosis under study Most of the distinctive auditory symptomatology these individuals exhibited is consequently attributable to disturbances within the central auditory nervous system Much of this symptomatology mimicked responses traditionally associated with inner ear lesions although some mimicked behavior induced by VIIIth nerve pathology Clearly it becomes necessary to rethink the diagnostic significance of the entire array of auditory tests when CNS lesions such as multiple sclerosis are a possibility This does not mean that test findings do not have the conventional meanings when encountered in the presence of peripheral auditory diseases and disorders It does mean that the same findings can have new meanings when CNS lesions are present Here too is an area where the further study of the auditory behavior of multiple sclerotic subjects coupled with good supporting data should prove most productive

Abstract

An extensive parametric study was conducted on the stimulus-related dc potentials of the cochlea (summating potential, SP). The potentials were measured from all three cochlear scalae, vestibuli (SV), tympani (ST) and media (SM) from the first three turns of guinea pig cochleae. Results are shown in terms of the potential gradient across the cochlear partition [DIF = SV − ST] and the common-mode potential of the perilymphatic space [AVE = (SV + ST)/2], as well as for the individual active electrodes. Aside from magnitude information, waveform patterns of the DIF, AVE, and SM potentials are also presented as functions of stimulus parameters. It is shown that there is a "best" frequency for any electrode location where at any stimulus level the DIF and SM responses are negative and the AVE response is positive. Below the best frequency the DIF and SM components are generally positive, while they vanish at higher frequencies. The AVE response is negative everywhere except within the best frequency region. The best frequency is approximately one octave above the frequency of the traveling wave maximum for a given cochlear site. Some preliminary hypotheses about the genesis of the various SP components are provided.

of important observations on SP. They recorded from the scala media of guinea pig cochleas with micropipettes, the reference electrode being in the scala tympani. They noted that upon passing through the organ of Corti with the pipette at the point of encountering the positive EP a polarity reversal of the SP occurred together with a phase inversion of the CM. This suggested to the authors, just as similar earlier observations on the CM suggested to Tasaki et al. (1954) that the potentials that reverse phase or polarity must be generated at the level where reversal takes place, that is, at the cilia bearing ends of the hair cells. It is unfortunate that Konishi & Yasuno did not elaborate on the experimental conditions that prevailed while the polarity reversal was observed. Specifically they did not indicate what the stimulus frequency or intensity were, or if these parameters could be varied while still obtaining the same result. Konishi & Yasuno also used polarizing currents to alter the SP response. Their results were quite complex and hard to interpret. One of their most important contributions was their attempt to obtain some parametric data on SP. They recorded input–output functions from the basal turn at eight different frequencies, and also SP vs frequency functions from all four turns at a constant (but unspecified) intensity. These functions reveal that the response tends to be negative in the turn that is most sensitive to the stimulus frequency; it also shows, contrary to earlier reports, that for frequencies that stimulate rather distant areas from the recording site the response is a large positive one. Butler et al. (1960) noted that the SP had a negative temperature coefficient as opposed to the normal positive temperature coefficient manifested by CM and EP. This observation suggested that the processes that generate CM and SP are different. Stopp & Whitfield (1964) made the important observation that the summating potential that could be recorded from the pigeon's cochlea had similar properties to the SP that was obtained from mammalian cochleas. Specifically, both SP+ and SP− were recordable. Since in the avian cochlea inner and outer hair cells are undifferentiated, Stopp & Whitfield's data mitigate against the hypothesis that the two different polarity SP are produced by different groups of hair cells. An important theoretical contribution to the problem of the SP production was made by Whitfield & Ross in 1965. These authors contend that the SP results from the nonlinearity of the CM generators, in other words, that it is merely the first component in a Fourier series that describes microphonic distortion. They noted that the apparent large size of the SP compared to the fundamental CM component, and even more so compared to higher harmonic components in CM, made the acceptance of the straightforward distortion hypothesis tenuous. In order to deal with this difficulty these authors postulated that due to the fact that a recording electrode picks up from a finite segment of the cochlea, and that within this segment there is a gradual phase change of the stimulus (i.e. of the traveling wave), CM generators contributing to the overall response are generally not in phase. The higher the frequency, the more rapid is the phase change. Since the CM voltages sum vectorally at the electrode location, high frequency responses will suffer an apparent diminution due to cancellations among out-of-phase generators. Such cancellation of course does not affect the SP; thus it is conceivable that the apparent size of the distortion component (SP) might be observed as being bigger than the distorted signal (CM) from which the former is derived in the process of nonlinear distortion. This ingenious argument certainly makes it possible to accept the distortion hypothesis for the genesis of SP, at least for certain portion of the SP. The distortion hypothesis was further espoused by Johnstone & Johnstone (1966) and by Engebretson & Eldredge (1968). The former authors derived a mathematical model for the generation of the SP; they showed that sinusoidal motion of the basilar membrane would always yield asymmetrical displacement of the cilia, and thus the means of producing SP. Another contribution was made by the latter authors who studied simple electrical models and demonstrated that

Introduction

In 1950 Davis, Fernández & McAuliffe and Békésy independently noted that a tonal stimulus can elicit a dc potential change in the cochlea During the decades following its discovery this dc cochlear response has been the subject of numerous investigations. These studies have clarified many properties of the response, but the most pervasive motif in the literature concerns the elusiveness of this potential and its propensity to defy quantification The best illustration of this fact in that it took nineteen years from its discovery for some published data to appear on the quantitative properties of the summating potential (SP) as this dc response became known over at least some range of pertinent parameter values (Honrubia & Ward 1969). The pioneering investigations of Davis and his colleagues culminated in a qualitative treatment of the subject (Davis et al., 1958*a*)

Apparently the major difficulty in settling the SP problem stems from the non unitary nature of this response. It was realized quite early that the SP is probably the sum of various components, originating in different physiological sites and processes (Davis et al., 1952 Goldstein 1954) Later only two components were emphasized, a positive (SP+) and a negative (SP−) summating potential (Davis et al 1958*a*) In their original communication Davis et al (1950) proposed that the SP is the electrical sign of the local excitatory process in the cochlear dendrites, that is excitatory postsynaptic potential (EPSP) While Davis et al. (1952) did extensive recordings with various combinations of intracochlear electrodes (such as scala tympani vs. vestibuli vestibuli vs indifferent, tympani vs. indifferent and intramodiolus vs. indifferent) they did not fully exploit the information contained in the comparison of responses obtained from the various combinations of recording sites. As we will attempt to demonstrate later such information might be the crucial factor in the unraveling of the complexities of the SP In 1957 Misrahy et al addressed themselves to the very pertinent problem whether or not the SP was a true physiological response or whether it might have been merely due to electrochemical reactions of the recording electrodes in the presence of loud sounds, or due to other artifactual conditions. They concluded that the SP was indeed a physiological response It was noted however that surgical injury such as escape of perilymph from the cochlea seemed to potentiate SP production. Because of this, they suggested that the " major factor influencing the summating potential maybe even its source is distortion within the cochlea." (p 4)

From a study of cochlear potentials modified by streptomycin poisoning and by venous obstruction, emerged the novel suggestion that the negative SP (as measured in scala media or scala vestibuli of the first turn of guinea pig cochleas) was primarily produced by the inner hair cells, while positive SP along with CM was assigned to the outer hair cells (Davis et al., 1958*b*) A summary paper by Davis et al (1958*a*) collected all known information about the SP The effect of anoxia upon cochlear potentials was extensively studied by Konishi et al (1961) Kiang & Peake (1960) introduced two interesting new methods into the study of SP using denervated cat cochleas as recording sites, and averaging computer techniques They noted that normal SP was not affected by the integrity of the cochlear nerve supply The authors also studied a "slow potential" that could be recorded at low sound intensities, and which was thought to be different from Davis SP Presumably this "slow potential is the same as SP In 1963 Konishi & Yasuno presented a number

of important observations on SP They recorded from the scala media of guinea pig cochleas with micropipettes, the reference electrode being in the scala tympani. They noted that upon passing through the organ of Corti with the pipette at the point of encountering the positive EP a polarity reversal of the SP occurred together with a phase inversion of the CM This suggested to the authors, just as similar earlier observations on the CM suggested to Tasaki et al (1954) that the potentials that reverse phase or polarity must be generated at the level where reversal takes place, that is, at the cilia-bearing ends of the hair cells. It is unfortunate that Konishi & Yasuno did not elaborate on the experimental conditions that prevailed while the polarity reversal was observed. Specifically they did not indicate what the stimulus frequency or intensity were, or if these parameters could be varied while still obtaining the same result. Konishi & Yasuno also used polarizing currents to alter the SP response Their results were quite complex and hard to interpret. One of their most important contributions was their attempt to obtain some parametric data on SP They recorded input–output functions from the basal turn at eight different frequencies, and also SP vs frequency functions from all four turns at a constant (but unspecified) intensity These functions reveal that the response tends to be negative in the turn that is most sensitive to the stimulus frequency it also shows, contrary to earlier reports, that for frequencies that stimulate rather distant areas from the recording site the response is a large positive one Butler et al. (1960) noted that the SP had a negative temperature coefficient as opposed to the normal positive temperature coefficient manifested by CM and EP This observation suggested that the processes that generate CM and SP are different. Stopp & Whitfield (1964) made the important observation that the summating potential that could be recorded from the pigeon's cochlea had similar properties to the SP that was obtained from mammalian cochleas. Specifically both SP+ and SP− were recordable. Since in the avian cochlea inner and outer hair cells are undifferentiated, Stopp & Whitfield's data mitigate against the hypothesis that the two different polarity SP are produced by different groups of hair cells. An important theoretical contribution to the problem of the SP production was made by Whitfield & Ross in 1965 These authors contend that the SP results from the nonlinearity of the CM generators, in other words, that it is merely the first component in a Fourier series that describes microphonic distortion. They noted that the apparent large size of the SP compared to the fundamental CM component, and even more so compared to higher harmonic components in CM made the acceptance of the straightforward distortion hypothesis tenuous. In order to deal with this difficulty these authors postulated that due to the fact that a recording electrode picks up from a finite segment of the cochlea, and that within this segment there is a gradual phase change of the stimulus (i.e. of the traveling wave), CM generators contributing to the overall response are generally not in phase. The higher the frequency the more rapid is the phase change. Since the CM voltages sum vectorially at the electrode location, high frequency responses will suffer an apparent diminution due to cancellations among out-of phase generators. Such cancellation of course does not affect the SP thus it is conceivable that the apparent size of the distortion component (SP) might be observed as being bigger than the distorted signal (CM) from which the former is derived in the process of nonlinear distortion. This ingenious argument certainly makes it possible to accept the distortion hypothesis for the genesis of SP at least for certain portion of the SP The distortion hypothesis was further espoused by Johnstone & Johnstone (1966) and by Engebretson & Eldredge (1968). The former authors derived a mathematical model for the generation of the SP they showed that sinusoidal motion of the basilar membrane would always yield asymmetrical displacement of the cilia, and thus the means of producing SP Another contribution was made by the latter authors who studied *simple* electrical models and demonstrated that

Introduction

In 1950 Davis, Fernández & McAuliffe and Békésy independently noted that a tonal stimulus can elicit a dc potential change in the cochlea. During the decades following its discovery this dc cochlear *response has been the subject of* numerous investigations. These studies have clarified many properties of the response but the most pervasive motif in the literature concerns the elusiveness of this potential and its propensity to defy quantification. The best illustration of this fact in that it took nineteen years from its discovery for some published data to appear on the quantitative properties of the summating potential (SP) as this dc response became known, over at least some range of pertinent parameter values (Honrubia & Ward 1969). The pioneering investigations of Davis and his colleagues culminated in a qualitative treatment of the subject (Davis et al 1958*a*).

Apparently the major difficulty in settling the SP problem stems from the non unitary nature of this response. It was realized quite early that the SP is probably the sum of various components, originating in different physiological sites and processes (Davis et al 1952, Goldstein 1954). Later, only two components were emphasized a positive (SP+) and a negative (SP−) *summating potential (Davis et al 1958a). In* their original communication Davis et al (1950) proposed that the SP is the electrical sign of the local excitatory process in the cochlear dendrites, that is excitatory postsynaptic potential (EPSP). While Davis et al (1952) did extensive recordings with various combinations of intracochlear electrodes (such as scala tympani vs vestibuli, vestibuli vs. indifferent, tympani vs. indifferent and intramodiolus vs. indifferent) they did not fully exploit the information contained in the comparison of responses obtained from the various combinations of recording sites. As we will attempt to demonstrate later such information might be the crucial factor in the unraveling of the complexities of the SP. In 1957 Misrahy et al addressed themselves to the very pertinent problem whether or not the SP was a true physiological response or whether it might have been merely due to electrochemical reactions of the recording electrodes in the presence of loud sounds, or due to other artifactual conditions. *They concluded that the SP was indeed a physiological* response, it was noted however, that surgical injury such as escape of perilymph from the cochlea seemed to potentiate SP production. Because of this, they suggested that the major factor influencing the summating potential maybe even its source is distortion within the cochlea. (p 4)

From a study of cochlear potentials modified by streptomycin poisoning and by venous obstruction, emerged the novel suggestion that the negative SP (as measured in scala media or scala vestibuli of the first turn of guinea pig cochleas) was primarily produced by *the inner* hair cells, while positive SP along with CM was assigned *to the outer hair cells (Davis et al* 1958*b*). A summary paper by Davis et al (1958*a*) collected all known information about the SP. *The effect of* anoxia upon cochlear potentials was extensively studied by Konishi et al (1961). Kiang & Peake (1960) introduced two interesting new methods into the study of SP using denervated cat cochleas as recording sites, and averaging computer techniques. They noted that normal SP was not affected by the integrity of the cochlear nerve supply. The authors also *studied a slow* potential" that could be recorded at low sound intensities, and which was thought to be different from Davis SP. Presumably this slow potential is the same as SP. In 1963 Konishi & Yasuno presented a number

recording from the perilymphatic scalae we have paid attention not only to the dc potential difference across the cochlear partition (the only potential that had interested earlier investigators), but also to the common dc potential of the two scalae. This common or average (AVE) potential component has evolved in the course of our studies as being just as significant as the potential gradient (Dallos et al., 1970), thus our data show that the common assumption that the SP polarity is opposite in scala vestibuli and tympani is not generally tenable. Aside from obtaining the two potential components (gradient and average) we have also compared these with the dc potentials recordable from scala media. Throughout the investigation we have used computer averaging methods that permitted data collection over a very wide range of signal intensities. Finally the total number of animals used in this experimental series (over 75) was large enough to permit us to report central tendencies in the data.

In the present report we wish to concentrate on the simple, quantitative description of the summating potential. The identification of the sources of the various subcomponents will comprise the subject of a future publication.

a number of nonlinear electrical phenomena that were known to exist in the cochlea (SP combination tone production and the interference effect) can be accounted for by the same nonlinearity Engebretson & Eldredge also suggest which we believe is a key point, that several nonlinear processes probably coexist in the cochlea, and these processes can account for the various (hard to-reconcile with a single source hypothesis) properties of the SP Kupperman (1966) further elaborated on the non unitary nature of SP He recorded from the scala tympani of all four turns of the guinea pig cochlea and focused his attention on the interaction between and the nature of the positive and negative SP He contends that the positive SP recorded from scala tympani (with the reference electrode in indifferent tissue) *from which the negative SP is subtracted out* would show strong localization to the site of maximum excitation This potential (pure positive SP as he called it) was regarded by Kupperman to be a manifestation of current flow between scalae media and tympani in the region of maximum stimulation. He regarded the negative SP in the scala tympani to be a sign of summated asynchronous neural potentials

Davis the discoverer of SP now regards it " as an incidental byproduct arising from asymmetry in the mechanism that produces cochlear microphonic rather than as a major physiological mechanism (Davis, 1968 p 652) Others are not so pessimistic about the possible function and significance of the SP Honrubia & Ward (1969) have recently completed a significant parametric study of the SP and they conclude that the negative SP is likely to act as a stimulus to the VIIIth nerve while the positive SP would probably be inhibitory These authors recorded SP with fine pipettes from the scala media in all four turns of the guinea pig cochlea. They varied signal intensity frequency and duration It was found that SP magnitude increased linearly with log-duration. The authors provided a number of plots giving the longitudinal distribution of SP as the function of stimulus frequency and intensity The familiar relationship again emerges that in the region of maximum stimulation the SP is negative *In all turns the* SP elicited by tones whose frequency was considerably below that favorable to the electrode location, the SP started out positive, went through a maximum with increased sound intensity decreased toward zero and finally turned negative at very high intensities. Those frequencies which were favorable to the electrode location elicited negative SP s even at relatively low intensities. One of the major limitations of this otherwise excellent study is that for technical reasons no data were obtained at low sound intensities (below approximately 65 dB)[1]

The review of the SP literature indicates that while there are salient properties of this potential about which there is a fairly general agreement, there are other aspects of this phenomenon *that are still unresolved* Except for the data of Konishi & Yasuno (1963), Honrubia & Ward (1969) and Kupperman (1966) most studies have been confined to studying the SP at high frequencies and high intensities The former two of these more complete investigations confined themselves to scala media recording, while the latter to describing scala tympani data There is a tacit assumption running through the entire literature that the SP is of oppposite polarity in scala vestibuli and tympani There is a severe paucity of information on the low intensity behavior of the SP Our work was designed to provide quantitative information on the properties of the SP from all three scalae of the first three turns of the guinea pig cochlea for a wide range of stimulus parameters. Since the SP is *apparently a multi-component* response, and since there is a very real probability that some of the components might play an important intermediary role in the process of peripheral information transfer we decided to reevaluate the entire SP phenomenon Aside from the purpose to provide extensive parametric information we have also endeavored to utilize recording techniques that enabled us to shed new light on this stimulus-related *dc potential* Specifically when

[1] All sound pressures in this paper are expressed in dB re 0.0002 dyne/cm²

recording from the perilymphatic scalae we have paid attention not only to the dc potential difference across the cochlear partition (the only potential that had interested earlier investigators), but also to the common dc potential of the two scalae. This common or average (AVE) potential component has evolved in the course of our studies as being just as significant as the potential gradient (Dallos et al., 1970), thus our data show that the common assumption that the SP polarity is opposite in scala vestibuli and tympani is not generally tenable. Aside from obtaining the two potential components (gradient and average) we have also compared these with the dc potentials recordable from scala media. Throughout the investigation we have used computer averaging methods that permitted data collection over a very wide range of signal intensities. Finally the total number of animals used in this experimental series (over 75) was large enough to permit us to report central tendencies in the data.

In the present report we wish to concentrate on the simple, quantitative description of the summating potential. The identification of the sources of the various subcomponents will comprise the subject of a future publication.

Methods

This article is based on data that were obtained from guinea pigs. Young animals (between 250 and 500 grams) were anesthetized with urethane, the tracheas were cannulated and the auditory bullae were approached with the customary ventro-lateral procedure The sound stimuli were delivered in a closed system to the bony meatus, they were monitored near the eardrum with a probe-tube microphone The tensor tympani tendon was severed in all animals, fine holes were drilled into the bony cochlea at appropriate locations and silver-silver chloride or tungsten electrodes were placed into these holes. The electrodes were held in place by cementing them to the bulla which was left open during the experiments. The electrodes were placed in pairs, one in scala vestibuli (SV) one in scala tympani (ST) of a given turn Often two pairs of electrodes were placed one pair always in the basal turn the other pair either in the second or the third turn of the cochlea. Each intracochlear electrode was connected to the non phase inverting input of a separate differential amplifier the phase-inverting inputs were connected to a common reference electrode (Ag AgCl disc wrapped in moist gauze) that was placed on the denuded neck muscles. The amplifier outputs could be recorded separately or two (one SV and the corresponding ST) could be added or subtracted The amplifiers provided 60 dB gain, their high frequency cut-off was 40 kHz, and the low frequency time constant was 3 sec In order to obtain SP recordings from the scala media a fine fenestra was made over stria vascularis of the appropriate turn by cutting the cochlear bone away with fine knives Care was taken not to damage the stria. After the bone was cleared away over a small area, a microelectrode (3M KCl filled pipette resistance 2–25 MOhms) was introduced into the scala media through the stria. The microelectrode was held in a flexible micromanipulator its final movement was controlled by a hydraulic microdrive The electrode was connected to a capacitance neutralized electrometer preamplifier the output of which was amplified and processed by the averaging computer The endocochlear potential (EP) was routinely measured at the beginning and at the end of the experiment The usual value was approximately +75 mV at the start, sometimes this value dropped to about +65 mV by the termination of the recording. Two types of cochlear response were measured the cochlear microphonic (CM) and the dc response to tone pips, the summating potential (SP) The CM was measured to ascertain the condition of the preparation before and during data collection to evaluate the adequacy of electrode placement, and to provide a familiar baseline for the dc potential measurements CM was measured in the form of isopotential curves, from individual electrodes and from differential pairs. We have described our criteria for evaluating the preparation on this basis in Dallos (1969) Median isopotential curves for the three electrode locations (turns I II and III) are shown in Fig. 1 these curves give a good measure of the spatial selectivity of the differential electrode pairs Most SP data reported in this paper are based on responses to tone pips of 40 msec duration, 100 msec interburst interval, and 1 msec rise fall time These parameters represent a compromise between excessively lengthy data collection time (that would result from longer burst and interburst durations) and the contamination of results by onset and cessation transients (that would result from shorter times) We have carefully evaluated the effect of time parameters on the SP as recorded from the perilymphatic scalae and on this basis we chose these values It appears that at the end of the 40 msec ON duration all significant on transients disappear

while the 100 msec OFF-duration allows the off-transients, including the afterpotential, to die out. For the SM measurements our customary parameters were changed to 60 msec ON and 200 msec OFF durations. We realize that in scala media the time constants are longer (Honrubia & Ward, 1969) but for measurements in SV and ST our parameters are appropriate, and for SM measurements they are acceptable even though they do not represent steady-state values.

All dc potential data were obtained by averaging the responses to several (between 16 and 1024) tone bursts. The carrier sinusoid was not phase-locked to the onset of the burst, consequently in the process of averaging both the CM and the low frequency time locked whole nerve action potential (AP) could be eliminated. No filtering was used, the computer process gives a cleaner and less equivocal representation of the dc potential than could be obtained by low-pass filtering. Another obvious advantage of computer processing is the improved signal-to-noise ratio and the consequent ability to evaluate responses at low sound levels. This process provides the true dc component of the signal as opposed to the customary method of evaluating the SP namely the measurement of the difference between the baseline and the center line of the peak-to-peak CM waveform. This latter process is very sensitive to the CM waveform itself and it can yield readings that bear no relation to the actual dc component of the aggregate response.

We have evaluated the possible effect of electrode polarization, by recording dc potentials from the cochlea with Ag AgCl and Tungsten electrodes placed within one millimeter from one-another in the basal turn The Ag–AgCl electrodes usually recorded a slightly greater dc potential magnitude, but for the stimulus parameters used in this study there was no discernible difference in the dynamic properties of the recorded response between the two electrodes. For this reason, and because tungsten electrodes can be made smaller and they are easier to fabricate these were used primarily during routine measurements from the perilymphatic scalae.

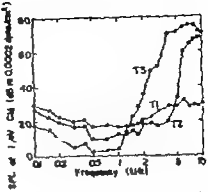

Fig 1 Median CM isopotential curves (sound pressure level required to produce 1 μV rms CM potential) obtained with differential electrodes from the three turns of the cochlea. The medians are based on 31 animals from turn-one, 13 from turn-two, and 18 from turn-three.

During surgery and during experiments the animals temperature was kept between 36–38°C with a warm water blanket the heating unit of which was controlled by a rectal thermometer The heart rate of the animals was monitored. Supplemental doses of anesthesia were administered when necessary

Before the results are described a terminology that is used throughout this paper must be introduced. When potentials are recorded from scala vestibuli or from scala tympani with reference to an electrode in indifferent tissue (the neck muscles) these will be denoted as SV and ST potentials respectively The potentials can be combined to yield two different kinds of information. When the difference $DIF = SV - ST$ or the sum $AVE = (SV + ST)/2$ are formed,

In our first report on this subject (Dallos et al., 1970) we defined the difference component in a somewhat different manner namely we had $DIF = (SV-ST)/2$. The reason for this choice was that when CM is recorded with differential electrodes in a situation where the stimulus frequency is tonotopically coincident with the electrode location, then the CM magnitude recorded from either scalae vestibuli or tympani is one-half of what is recorded with both electrodes connected to a differential amplifier The introduction of the compensating factor of one-half is not really necessary since as one can appreciate with the circuit of Fig 2a, the individual electrodes in this case record voltage drops that are one-half of the source voltage. Consequently the actual potential gradient, reflected by the differential electrode output, is a better representation of the source voltage than the single electrode response.

Methods

This article is based on data that were obtained from guinea pigs. Young animals (between 250 and 500 grams) were anesthetized with urethane, the tracheas were cannulated and the auditory bullae were approached with the customary ventro-lateral procedure. The sound stimuli were delivered in a closed system to the bony meatus, they were monitored near the eardrum with a probe-tube microphone. The tensor tympani tendon was severed in all animals, fine holes were drilled into the bony cochlea at appropriate locations and silver-silver chloride or tungsten electrodes were placed into these holes. The electrodes were held in place by cementing them to the bulla which was left open during the experiments. The electrodes were placed in pairs, one in scala vestibuli (SV) one in scala tympani (ST) of a given turn. Often two pairs of electrodes were placed one pair always in the basal turn the other pair either in the second or the third turn of the cochlea. Each intracochlear electrode was connected to the non phase inverting input of a separate differential amplifier the phase inverting inputs were connected to a common reference electrode (Ag AgCl disc wrapped in moist gauze) that was placed on the denuded neck muscles. The amplifier outputs could be recorded separately or two (one SV and the corresponding ST) could be added or subtracted. The amplifiers provided 60 dB gain their high frequency cut-off was 40 kHz, and the low frequency time constant was 3 sec. In order to obtain SP recordings from the scala media a fine fenestra was made over stria vascularis of the appropriate turn by cutting the cochlear bone away with fine knives. Care was taken not to damage the stria. After the bone was cleared away over a small area, a microelectrode (3M KCl filled pipette, resistance 2–75 MOhms) was introduced into the scala media through the stria. The microelectrode was held in a flexible micromanipulator its final movement was controlled by a hydraulic microdrive. The electrode was connected to a capacitance neutralized electrometer preamplifier the output of which was amplified and processed by the averaging computer. The endocochlear potential (EP) was routinely measured at the beginning and at the end of the experiment. The usual value was approximately +75 mV at the start sometimes this value dropped to about +65 mV by the termination of the recording. Two types of cochlear response were measured the cochlear microphonic (CM) and the dc response to tone pips, the summating potential (SP). The CM was measured to ascertain the condition of the preparation before and during data collection, to evaluate the adequacy of electrode placement and to provide a familiar baseline for the dc potential measurements. CM was measured in the form of isopotential curves, from individual electrodes and from differential pairs. We have described our criteria for evaluating the preparation on this basis in Dallos (1969). Median isopotential curves for the three electrode locations (turns I II and III) are shown in Fig. 1 these curves give a good measure of the spatial selectivity of the differential electrode pairs. Most SP data reported in this paper are based on responses to tone pips of 40 msec duration, 100 msec interburst interval and 1 msec rise-fall time. These parameters represent a compromise between excessively lengthy data collection time (that would result from longer burst and interburst durations) and the contamination of results by onset and cessation transients (that would result from shorter times). We have carefully evaluated the effect of time parameters on the SP as recorded from the perilymphatic scalae and on this basis we chose these values. It appears that at the end of the 40 msec ON duration all significant on transients disappear

while the 100 msec OFF-duration allows the off-transients, including the afterpotential, to die out. For the SM measurements our customary parameters were changed to 60 msec ON and 200 msec OFF durations. We realize that in scala media the time constants are longer (Honrubia & Ward, 1969) but for measurements in SV and ST our parameters are appropriate, and for SM measurements they are acceptable even though they do not represent steady-state values.

All dc potential data were obtained by averaging the responses to several (between 16 and 1024) tone bursts. The carrier sinusoid was not phase-locked to the onset of the burst, consequently in the process of averaging both the CM and the low frequency time locked whole nerve action potential (AP) could be eliminated. No filtering was used, the computer process gives a cleaner and less equivocal representation of the dc potential than could be obtained by low-pass filtering. Another obvious advantage of computer processing is the improved signal-to-noise ratio and the consequent ability to evaluate responses at low sound levels. This process provides the true dc component of the signal as opposed to the customary method of evaluating the SP namely the measurement of the difference between the baseline and the center line of the peak-to-peak CM waveform. This latter process is very sensitive to the CM waveform itself and it can yield readings that bear no relation to the actual dc component of the aggregate response.

We have evaluated the possible effect of electrode polarization, by recording dc potentials from the cochlea with Ag AgCl and Tungsten electrodes placed within one millimeter from one-another in the basal turn. The Ag AgCl electrodes usually recorded a slightly greater dc potential magnitude, but for the stimulus parameters used in this study there was no discernible difference in the dynamic properties of the recorded response between the two electrodes. For this reason, and because tungsten electrodes can be made smaller and they are easier to fabricate, these were used primarily during routine measurements from the perilymphatic scalae.

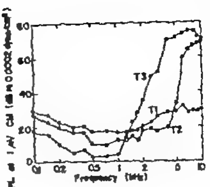

Fig. 1. Median CM isopotential curves (sound pressure level required to produce 1 µV rms CM potential) obtained with differential electrodes from the three turns of the cochlea. The medians are based on 31 animals from turn-one, 13 from turn-two, and 18 from turn-three.

During surgery and during experiments the animals temperature was kept between 36–38°C with a warm water blanket the heating unit of which was controlled by a rectal thermometer. The heart rate of the animals was monitored. Supplemental doses of anesthesia were administered when necessary.

Before the results are described, a terminology that is used throughout this paper must be introduced. When potentials are recorded from scala vestibuli or from scala tympani with reference to an electrode in indifferent tissue (the neck muscles) these will be denoted as SV and ST potentials respectively. The potentials can be combined to yield two different kinds of information. When the difference DIF = SV − ST or the sum AVE = (SV + ST)/2 are formed.[1]

[1] In our first report on this subject (Dallos et al. 1970) we defined the difference component in a somewhat different manner namely we had DIF = (SV−ST)/2. The reason for this choice was that when CM is recorded with differential electrodes in a situation where the stimulus frequency is tonotopically coincident with the electrode location, then the CM magnitude recorded from either scalae vestibuli or tympani is one-half of what is recorded with both electrodes connected to a differential amplifier. The introduction of the compensating factor of one-half is not really necessary since as one can appreciate with the circuit of Fig. 2 the individual electrodes in this case record voltage drops that are one-half of the source voltage. Consequently the actual potential gradient, reflected by the differential electrode output, is a better representation of the source voltage than the single electrode response.

Methods

This article is based on data that were obtained from guinea pigs Young animals (between 250 and 500 grams) were anesthetized with urethane, the tracheas were cannulated and the auditory bullae were approached with the customary ventro-lateral procedure. The sound stimuli were delivered in a closed system to the bony meatus, they were monitored near the eardrum with a probe tube microphone The tensor tympani tendon was severed in all animals, fine holes were drilled into the bony cochlea at appropriate locations and silver-silver chloride or tungsten electrodes were placed into these holes The electrodes were held in place by cementing them to the bulla which was left open during the experiments. The electrodes were placed in pairs, one in scala vestibuli (SV) one in scala tympani (ST) of a given turn Often two pairs of electrodes were placed, one pair always in the basal turn the other pair either in the second or the third turn of the cochlea. Each intracochlear electrode was connected to the non phase inverting input of a separate differential amplifier the phase inverting inputs were connected to a common reference electrode (Ag AgCl disc wrapped in moist gauze) that was placed on the denuded neck muscles. The amplifier outputs could be recorded separately or two (one SV and the corresponding ST) could be added or subtracted The amplifiers provided 60 dB gain, their high frequency cut-off was 40 kHz, and the low frequency time constant was 3 sec In order to obtain SP recordings from the scala media a fine fenestra was made over stria vascularis of the appropriate turn by cutting the cochlear bone away with fine knives Care was taken not to damage the stria. After the bone was cleared away over a small area, a microelectrode (3M KCl filled pipette, resistance 2–25 MOhms) was introduced into the scala media through the stria. The microelectrode was held in a flexible micromanipulator its final movement was controlled by a hydraulic microdrive The electrode was connected to a capacitance neutralized electrometer preamplifier the output of which was amplified and processed by the averaging computer The endocochlear potential (EP) was routinely measured at the beginning and at the end of the experiment. The usual value was approximately +75 mV at the start sometimes this value dropped to about +65 mV by the termination of the recording. Two types of cochlear response were measured the cochlear microphonic (CM) and the dc response to tone pips, the summating potential (SP). The CM was measured to ascertain the condition of the preparation before and during data collection, to evaluate the adequacy of electrode placement and to provide a familiar baseline for the dc potential measurements CM was measured in the form of isopotential curves, from individual electrodes and from differential pairs. We have described our criteria for evaluating the preparation on this basis in Dallos (1969). Median isopotential curves for the three electrode locations (turns I II and III) are shown in Fig 1 these curves give a good measure of the spatial selectivity of the differential electrode pairs. Most SP data reported in this paper are based on responses to tone pips of 40 msec duration 100 msec interburst interval and 1 msec rise fall time These parameters represent a compromise between excessively lengthy data collection time (that would result from longer burst and interburst durations) and the contamination of results by onset and cessation transients (that would result from shorter times) We have carefully evaluated the effect of time parameters on the SP as recorded from the perilymphatic scalae, and on this basis we chose these values It appears that at the end of the 40 msec ON duration all significant on transients disappear

evaluated by taking the difference between the baseline and the average magnitude of the SP during the final five milliseconds of the response. For SM recordings, where the response had not reached its final value by the end of the 60 msec duration of the stimulus, the SP was measured as the difference between the baseline and the actual value of the response at the cessation of the signal.

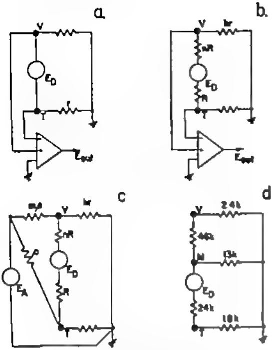

Fig 2 Various equivalent electrical circuits that are discussed in the text In all four circuits the same symbols are used the nodes *T V* and *M* designate the recording points in scalae tympani, vestibuli and media, the generator E_D symbolizes the voltage source within the organ of Corti, while E_A is an extra-partition remote source (*a*) Equivalent circuit of a completely symmetrical differential electrode recording situation. The voltage at node *V* is $E_D/2$, while at node *T* it is $-E_D/2$. Hence the voltage differential $\mathrm{DIF} = E_{OUT} = E_V - E_T = E_D$. (*b*) Schema of the differential electrode recording scheme when the various circuit elements are asymmetrical (*c*) Simplified scheme of the differential electrode recording scheme when both local and remote sources are active and when all circuit elements are asymmetrical (*d*) Equivalent circuit of a cochlear cross section. Resistance values after Johnstone et al., 1966.

these are analogous to the potentials obtained classically with the differential electrode technique when AP or CM are respectively minimized The usual interpretation of the results of the differential electrode recordings under those two conditions is that the former emphasizes the local response (different polarity for the two electrodes across the cochlear partition) or the remote response (same polarity for the two electrodes), (Tasaki et al 1952 Teas et al 1962) For our purposes these potentials, DIF and AVE, are construed as follows. The DIF potential is proportional to the potential difference across the cochlear partition and to a good approximation this quantity describes the *locally generated voltage* that is one whose source is located between the electrode tips. The AVE response is proportional to the *common potential* of the two scalae Ordinarily this response is associated with remote activity but aside from this, we tend to look at this potential as either being proportional to a voltage drop created by longitudinal current flow which is in the same direction in both scalae vestibuli and tympani or one that reflects the asymmetry of cochlear electroanatomy or both. Both operations, DIF = SV − ST and AVE = (SV + ST)/2 can be, and have been performed either electronically during the experiment, or graphically or arithmetically from the SV and ST data. Either method yields essentially the same result. We are presenting data on the pages to follow in both forms SV and ST or DIF and AVE. When either form is given the other can be obtained by simple computation The relative independence of the DIF and AVE components is considered in detail in the Discussion section of this paper It will be emphasized that it is difficult to reliably record one of these components if it is small provided that the other component is very large We will see for example that the DIF component that is recorded from the higher cochlear turns at high frequencies is quite small and does not seem to show a clear pattern of change with signal parameters. At the same time the AVE component is rather large In this situation the DIF component that one records is probably nothing more than an artifact resulting from imperfect electrode placement The greater the disparity between DIF and AVE is in a given recording situation the more reliable the recording is for the larger and the less reliable it is for the smaller component

The final comment in this section concerns the actual evaluation of the data. The SP information was obtained from the averaging computer in the form of X–Y plots that is, SP magnitude plotted as the function of time Since the SP waveform changes during the presence of the stimulus it was necessary to establish a set procedure for obtaining the SP magnitude from the plots All SV ST DIF and AVE data were

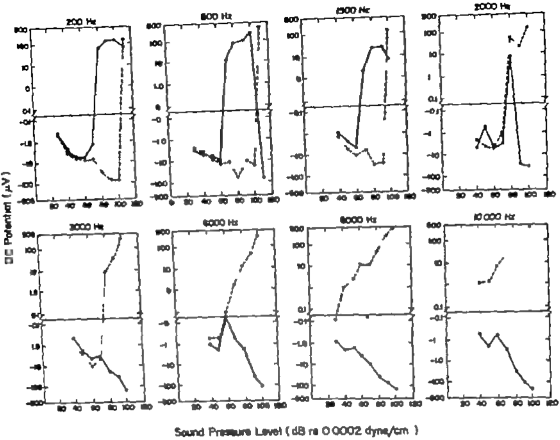

Fig. 3. Median SP input-output functions at various frequencies from scala vestibuli (●—●) and scala tympani (○—○) of the first cochlear turn.

tion is in harmony with descriptions of the SP in the literature, in fact it is this potential, positive in ST negative in SV that is traditionally regarded as the SP–. It is often said that the SP is positive (i.e. SV is positive re ST) at low intensities. Our plots show that this is correct but not universally. We see the SV-positive, ST-negative combination at the mid-intensities and only at low frequencies. We further see that except at the highest frequencies, both scalae of the basal turn are negative at the lowest intensities. This observation is significant on two counts: first it is a new observation not hitherto noted; second, it is contrary to the very common assumption in the literature that the polarities of the two scalae are always opposite.

Let us now recast these data into the DIF = SV – ST and the AVE = (SV + ST)/2 components. In Fig. 4 these plots are seen. Note first that the AVE pattern is somewhat similar at the lower frequencies. At very high intensities the AVE potential is positive in the base at all frequencies, at lesser SPLs it turns negative and stays negative.

The exceptional frequency is 10 000 Hz where the average potential of the two scalae is positive at *all* intensities. The DIF plots depict a complete and orderly transition from low to high frequencies. At 200 Hz the local response is positive at all SPLs, while it is negative at all SPLs at the highest frequency tested. In between a transition takes place in that at high intensities the DIF potential turns negative, this occurs at lower intensities as the frequency increases. It

MAGNITUDE AND POLARITY OF THE SP

Unless otherwise indicated the plots depicting SP magnitude as the function of various parameters are median plots. Data points are obtained as the median value of individual data that are available for a given experimental condition. The number of experimental animals that contribute to a given median datum is not the same fewer points are available at the extremes of the intensity range for example, and fewer points from the third cochlear turn than from the first. The range of the number of animals whose responses were used for obtaining a given point was between 3 and 19 the majority being between 5 and 7

Let us first consider the response patterns in the form of input–output functions, that is SP magnitude versus sound intensity at any given frequency and electrode location. In Fig. 3 a set of such functions is shown for basal turn electrodes, both SV and ST responses are included The eight pairs of plots depict the variation of SP as the frequency changes from 200 to 10 000 Hz and as the signal intensity changes between 40 and 100 dB sound pressure level (SPL) Note that these are log–log plots the ordinate gives the SP magnitude in μV over a $\pm$80 dB range, while the abscissa is expressed in dB re 0 0002 dyne/cm² At 200 Hz, below 70 dB SPL, *both* SV and ST electrodes register negative potentials, moreover below 60 dB they see approximately the same potential magnitude Above 70 dB the SV potential turns positive while the ST potential remains negative Above approximately 80 dB the absolute value of the SV potential exceeds that of the ST one If the sound intensity is further increased beyond 100 dB SPL, another polarity reversal can be seen at approximately 110 dB the ST potential goes positive and at even higher SPL s the SV potential would go negative The picture then would be similar to what is seen for 500 Hz. At this latter frequency the character of the response is quite like that at 200 Hz at very low SPLs both electrodes see about equal negativity around 70 dB the SV electrode becomes positive but here a second reversal occurs within the depicted range. At approximately 105 dB both scalae reverse their polarity As stimulus frequency further increases, the pattern seen for 500 Hz undergoes a gradual change into the pattern shown for the 3 000 Hz condition This change involves the disappearance of the positive hump for the SV electrode which is now negative at *all* SPLs, and the gradual lowering of the cross over point of the ST potential Note that here as well as in the following plot (for 6 000 Hz) we still see *both* scalae at the approximately identical negative potential level at the lowest intensities. Attention is called to the very consistent slight inflexion or reversal in the SV potential plot at approximately 60 dB which is of course the level where this scala turned positive at lesser frequencies. The overall pattern seen at 3 000 Hz continues at 6 000 Hz, the only difference is that the ST-cross over occurs at a lower intensity This process continues as frequency is raised until as shown in the 8 000 Hz plot the SV is negative while the ST is positive at all intensity levels. The 10 000 Hz plot is almost identical at least it appears so actually there are important albeit subtle differences between them as will be seen in the DIF and AVE plots of these same data

The plots of Fig. 3 reveal a very consistent and systematic shift in the SP pattern from low to high frequencies and from low to high intensities. The following salient features are worth mentioning. At very high intensities, irrespective of frequency the basal SV potential is negative the basal ST potential is positive This observa

MAGNITUDE AND POLARITY OF THE SP

Unless otherwise indicated the plots depicting SP magnitude as the function of various parameters are median plots. Data points are obtained as the median value of individual data that are available for a given experimental condition. The number of experimental animals that contribute to a given median datum is not the same, fewer points are available at the extremes of the intensity range for example, and fewer points from the third cochlear turn than from the first. The range of the number of animals whose responses were used for obtaining a given point was between 3 and 19, the majority being between 5 and 7.

Let us first consider the response patterns in the form of input–output functions, that is SP magnitude versus sound intensity at any given frequency and electrode location. In Fig. 3 a set of such functions is shown for basal turn electrodes, both SV and ST responses are included. The eight pairs of plots depict the variation of SP as the frequency changes from 200 to 10 000 Hz and as the signal intensity changes between 40 and 100 dB sound pressure level (SPL). Note that these are log–log plots, the ordinate gives the SP magnitude in μV over a ± 80 dB range, while the abscissa is expressed in dB *re* 0.0002 dyne/cm^2. At 200 Hz, below 70 dB SPL, *both* SV and ST electrodes register negative potentials, moreover, below 60 dB they see approximately the same potential magnitude. Above 70 dB the SV potential turns positive while the ST potential remains negative. Above approximately 80 dB the absolute value of the SV potential exceeds that of the ST one. If the sound intensity is further increased beyond 100 dB SPL, another polarity reversal can be seen at approximately 110 dB the ST potential goes positive and at even higher SPLs the SV potential would go negative. The picture then would be similar to what is seen for 500 Hz. At this latter frequency the character of the response is quite like that at 200 Hz, at very low SPLs both electrodes see about equal negativity, around 70 dB the SV electrode becomes positive, but here a second reversal occurs within the depicted range. At approximately 105 dB both scalae reverse their polarity. As stimulus frequency further increases, the pattern seen for 500 Hz undergoes a gradual change into the pattern shown for the 3 000 Hz condition. This change involves the disappearance of the positive hump for the SV electrode, which is now negative at *all* SPLs, and the gradual lowering of the cross-over point of the ST potential. Note that here as well as in the following plot (for 6 000 Hz) we still see *both* scalae at the approximately identical negative potential level at the lowest intensities. Attention is called to the very consistent slight inflexion or reversal in the SV potential plot at approximately 60 dB, which is of course the level where this scala turned positive at lesser frequencies. The overall pattern seen at 3 000 Hz continues at 6 000 Hz, the only difference is that the ST-cross over occurs at a lower intensity. This process continues as frequency is raised, until as shown in the 8 000 Hz plot, the SV is negative while the ST is positive at all intensity levels. The 10 000 Hz plot is almost identical, at least it appears so, actually there are important albeit subtle differences between them as will be seen in the DIF and AVE plots of these same data.

The plots of Fig. 3 reveal a very consistent and systematic *shift in the SP pattern from low to high frequencies* and from low to high intensities. The following salient features are worth mentioning. At very high intensities, irrespective of frequency, the basal SV potential is negative, the basal ST potential is positive. This observa

tion is in harmony with descriptions of the SP in the literature, in fact it is this potential, positive in ST negative in SV that is traditionally regarded as the SP− It is often said that the SP is positive (i.e. SV is positive re ST) at low intensities. Our plots show that this is correct but not universally. We see the SV-positive, ST negative combination at the mid-intensities and only at low frequencies. We further see that except at the highest frequencies, both scalae of the basal turn are negative at the lowest intensities. This observation is significant on two counts: first it is a new observation not hitherto noted, second, it is contrary to the very common assumption in the literature that the polarities of the two scalae are always opposite.

Let us now recast these data into the DIF = SV − ST and the AVE = (SV + ST)/2 components. In Fig. 4 these plots are seen. Note first that the AVE pattern is somewhat similar at the lower frequencies. At very high intensities the AVE potential is positive in the base at all frequencies, at lesser SPLs it turns negative and stays negative.

The exceptional frequency is 10 000 Hz where the average potential of the two scalae is positive at *all* intensities. The DIF plots depict a complete and orderly transition from low to high frequencies. At 200 Hz the local response is positive *at all SPLs*, while it is negative at all SPLs at the highest frequency tested. In between a transition takes place in that at high intensities the DIF potential turns negative, this occurs at lower intensities as the frequency increases. It

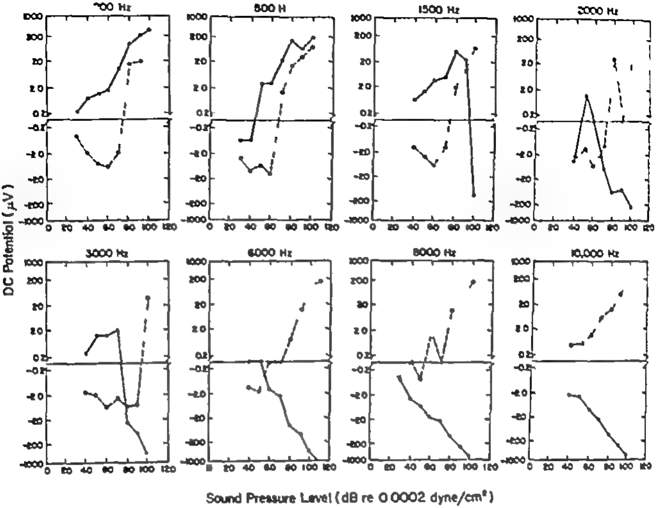

Fig 4 Median SP input-output functions at various frequencies from the first cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

should be noted that even at 200 Hz if we would have shown the situation at much higher SPL s the DIF response would be negative This transition at 200 Hz would occur at approximately 110 dB at higher intensities for lower frequencies. One can summarize by saying that the local potential (DIF response) is negative at *all* frequencies if the intensity is made high enough This negativity is seen at lesser and lesser intensities with the increase in frequency The local response stays negative at all intensities at high frequencies, but it turns positive at lower frequencies and at lower intensities. This low level positivity and high level negativity corresponds to the traditionally expressed SP and SP Some important new observations arise from the data shown in Fig 4 These observations primarily involve the AVE potential that has not been paid any attention in the literature This potential as we now see is always negative at low intensities, except (as we will see in more detail) in a narrow frequency range near the "best" frequency of a given electrode location, where it is positive at all SPLs. It is also seen that at high intensities the AVE potential is always positive

Let us now turn our attention to SP data recorded from the second turn of the guinea pig s cochlea Again a series of input-output functions are shown in Fig 5 for both the SV and ST electrodes. These plots appear somewhat more complex than those for the first turn, but close scrutiny reveals that very systematic changes in the SP exist here too with variation of both fre-

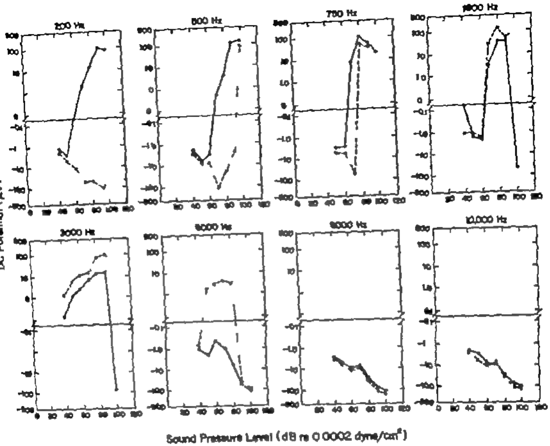

Fig. 5. Median input-output functions at various frequencies from scala vestibuli (●—●) and scala tympani (○ – ○) of the second cochlear turn

quency and intensity. First, let us note that up to 1 500 Hz, at the lowest SPLs both SV and ST potentials are negative and approximately equal in magnitude. Similar observation was made in the basal turn situation, but for a wider frequency range. At 200 Hz, after this initial negativity the SV electrode goes positive at approximately 60 dB SPL, while the ST electrode increases its negativity. At 500 and 750 Hz the SV pattern is similar to the one at 200 Hz.

The ST potential exhibits a progressive change from 200 to 3 000 Hz. Below 500 Hz the ST potential is always negative. At 500 Hz the ST potential turns positive at 90 dB SPL, the turn-over occurs at about 75 and 65 dB between 750 and 1 500 Hz, while at 3 000 Hz the ST is always positive. At 1 500 Hz we see another trend develop, the SV potential goes negative at high intensities, by 6 000 Hz it is always negative even though a clear transition between two zones is seen at 60–70 dB. At 8 0000 and 10 000 Hz both electrodes are measuring approximately equal negative potentials that gradually increase with stimulus intensity. Here again we must point out that the data clearly show that the two scalae of the same turn do not always have potentials of opposite polarity. In fact, at low frequencies and low intensities the two scalae are about equally negative, and at high frequencies at all intensities the two scalae are again about equally negative. At very low frequencies and at relatively high intensities the SV is positive, the ST is negative, while if we would have shown in this figure potentials for

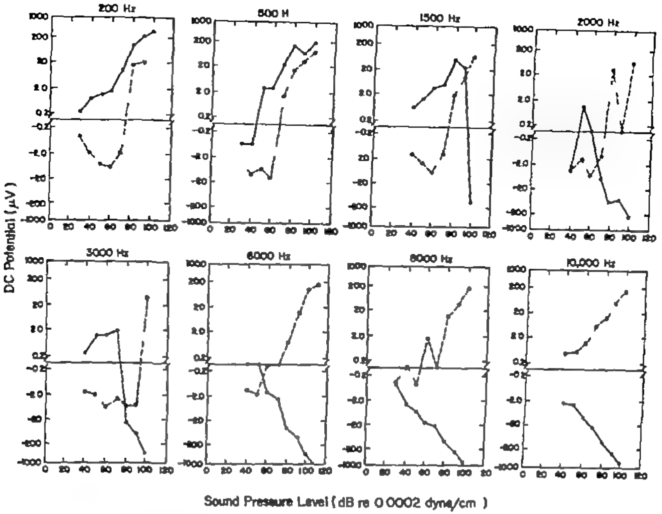

Fig 4 Median SP input-output functions at various frequencies from the first cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

should be noted that even at 200 Hz if we would have shown the situation at much higher SPL s the DIF response would be negative This transition at 200 Hz would occur at approximately 110 dB at higher intensities for lower frequencies. One can summarize by saying that the local potential (DIF response) is negative at *all* frequencies if the intensity is made high enough This negativity is seen at lesser and lesser intensities with the increase in frequency The local response stays negative at all intensities at high frequencies, but it turns positive at lower frequencies and at lower intensities. This low level positivity and high level negativity corresponds to the traditionally expressed SP^+ and SP^- Some important new observations arise from the data shown in Fig. 4 These observations primarily involve the AVE potential that has not been paid any attention in the literature This potential as we now see is always negative at low intensities, except (as we will see in more detail) in a narrow frequency range near the "best frequency of a given electrode location, where it is positive at all SPLs. It is also seen that at high intensities the AVE potential is always positive.

Let us now turn our attention to SP data recorded from the second turn of the guinea pig s cochlea. Again a series of input–output functions are shown in Fig 5 for both the SV and ST electrodes. These plots appear somewhat more complex than those for the first turn, but close scrutiny reveals that very systematic changes in the SP exist here too with variation of both fre

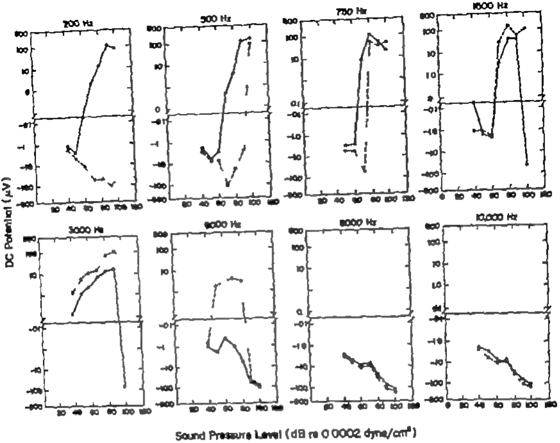

Fig. 5. Median input-output functions at various frequencies from scala vestibuli (●—●) and scala tympani (○ – ○) of the second cochlear turn.

quency and intensity. First, let us note that up to 1 500 Hz, at the lowest SPLs both SV and ST potentials are negative and approximately equal in magnitude. Similar observation was made in the basal turn situation, but for a wider frequency range. At 200 Hz, after this initial negativity the SV electrode goes positive at approximately 60 dB SPL, while the ST electrode increases its negativity. At 500 and 750 Hz the SV pattern is similar to the one at 200 Hz.

The ST potential exhibits a progressive change from 200 to 3 000 Hz. Below 500 Hz the ST potential is always negative. At 500 Hz the ST potential turns positive at 90 dB SPL, the turnover occurs at about 75 and 65 dB between 750 and 1 500 Hz, while at 3 000 Hz the ST is always positive. At 1 500 Hz we see another trend develop, the SV potential goes negative at high intensities, by 6 000 Hz it is always negative even though a clear transition between two zones is seen at 60–70 dB. At 8 0000 and 10 000 Hz both electrodes are measuring approximately equal negative potentials that gradually increase with stimulus intensity. Here again we must point out that the data clearly show that the two scalae of the same turn do *not* always have potentials of opposite polarity. In fact, at low frequencies and low intensities the two scalae are about equally negative, and at high frequencies at all intensities the two scalae are again about equally *negative*. At very low frequencies and at relatively high intensities the SV is positive, the ST is negative, while if we would have shown in this figure potentials for

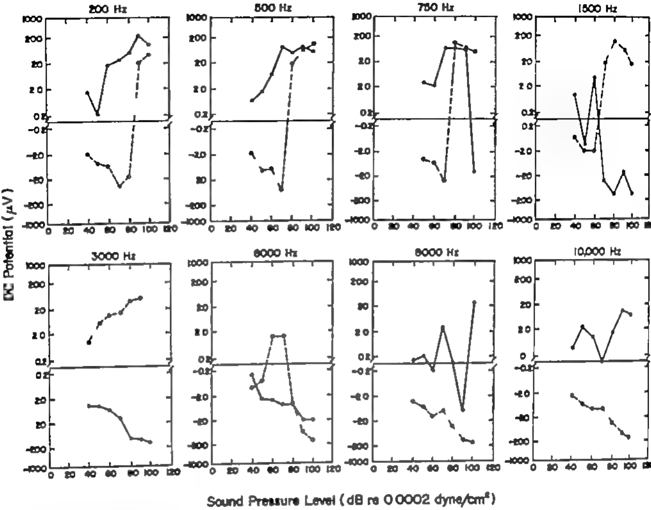

Fig 6 Median SP input–output functions at various frequencies from the second cochlear turn Plots are given for the DIF (●—●) and AVE (○—○) components.

intensities well above 100 dB we would have seen an additional reversal at low frequencies, whereby the SV would have become negative, the ST positive It is remembered that this situation is very much as that seen in the basal turn.

When the data are recast to show local DIF and common AVE responses, we obtain Fig. 6 At the lowest frequencies the local response is small at low sound levels, and is positive at higher intensities The AVE response at these low frequencies starts out negative increases its magnitude then crosses over into the positive region at progressively lower and lower SPL s as frequency is increased At 750 Hz we notice the beginning of another trend The DIF response starts to move negative, first at high SPLs only but by 3 000 Hz it is negative at all levels Above 3 000 Hz the DIF response becomes smaller and by 8 000 and 10 000 Hz it is negligible[1] The initial negativity of the AVE

[1] It is important to explain, and to clearly understand the contention that the DIF component is negligible in the 8 and 10 kHz plots. To do this, attention is called to the Discussion concerning expected errors in DIF or AVE components whenever one of these components is considerably in excess of the other When such disparities exist, the smaller of the two components cannot be measured accurately if even minor asymmetries are present between SV and ST recordings. One almost invariably must contend with such asymmetries, thus the safest procedure is to disregard a component if it is much smaller than the other and if this component appears to fluctuate unsystematically about zero voltage. The DIF component at 8 and 10 kHz has these characteristics, it is most likely not a true response but merely a manifestation of experimental error This contention can be underscored by examining the individual electrode responses at these

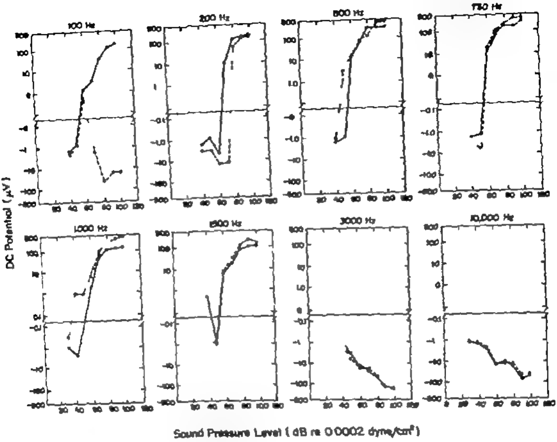

Fig. 7 Median input–output functions at various frequencies from scala vestibuli (●—●) and scala tympani (○—○) of the third cochlear turn

response becomes less and less pronounced as frequency increases between 500 and 1 300 Hz, and at 3 000 Hz this response component is positive at all intensities. Above 6 000 Hz the AVE response reverses once again, and at the highest frequencies it is uniformly negative.

Let us now turn to recordings from the third turn, first the potentials from SV and ST are examined then DIF and AVE components are discussed. In Fig. 7 the potentials seen by the individual electrodes are shown in the now familiar format of input–output functions. The first, very striking observation is that in contrast

ts frequencies. It is notable that the electrodes record virtually the same potentials, indicating the nonsignificant contribution of potential difference to the recorded responses.

with recordings from the lower turns, where in general the two electrodes picked up considerably different potentials, here they tend to see similar responses. At the lowest frequencies the responses from both electrodes are negative and approximately equal at low intensities. This behavior we recall is the same in all three turns. The SV electrode turns positive at approximately 60 dB SPL up to 1 000 Hz, above that this positivity eventually disappears. The ST electrode shows a considerable change at low frequencies at 100 Hz it is negative at the lowest and highest intensities, with the increase in frequency it goes positive at the mid-intensities. At 3 000 Hz and above, both electrodes are negative and equal in potential magnitude

The DIF and AVE p... (Fig. 8) shows that

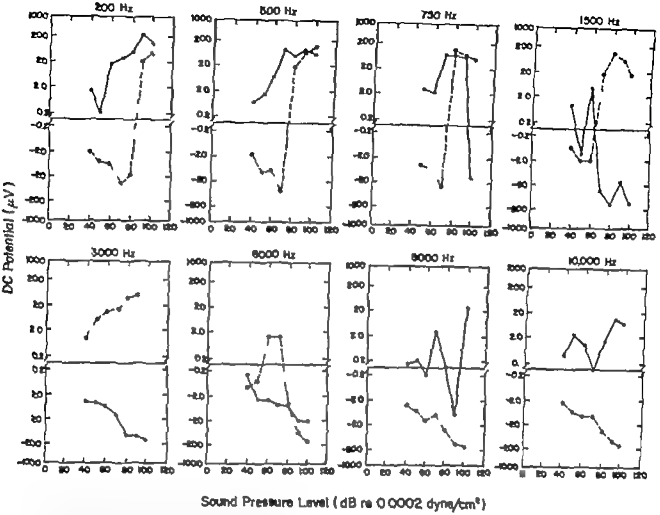

Fig 6 Median SP input–output functions at various frequencies from the second cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

intensities well above 100 dB we would have seen an additional reversal at low frequencies, whereby the SV would have become negative, the ST positive It is remembered that this situation is very much as that seen in the basal turn

When the data are recast to show local DIF and common AVE responses we obtain Fig 6 At the lowest frequencies the local response is small at low sound levels, and is positive at higher intensities The AVE response at these low frequencies starts out negative, increases its magnitude, then crosses over into the positive region at progressively lower and lower SPL s as frequency is increased At 750 Hz we notice the beginning of another trend The DIF response starts to move negative first at high SPLs only but by 3 000 Hz it is negative at all levels Above 3 000 Hz the DIF response becomes smaller and by 8 000 and 10 000 Hz it is negligible [1] The initial negativity of the AVE

[1] It is important to explain, and to clearly understand, the contention that the DIF component is negligible in the 8 and 10 kHz plots To do this attention is called to the Discussion concerning expected errors in DIF or AVE components whenever one of these components is considerably in excess of the other When such disparities exist the smaller of the two components cannot be measured accurately if even minor asymmetries are present between SV and ST recordings. One almost invariably must contend with such asymmetries, thus the safest procedure is to disregard a component if it is much smaller than the other and if this component appears to fluctuate unsystematically about zero voltage. The DIF component at 8 and 10 kHz has these characteristics, it is most likely not a true response but merely a manifestation of experimental error This contention can be underscored by examining the individual electrode responses at these

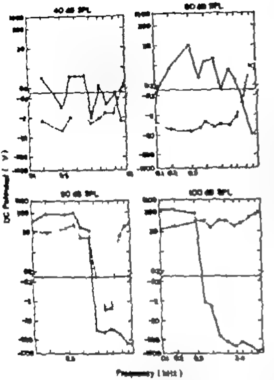

Fig. 9. Median SP versus stimulus frequency functions at several signal intensities from the first cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

to sufficiently high frequencies. The zone of ajor importance is the one around the best fre- ency of the recording electrode. In this zone e local response is negative. The best fre ency could be identified by the maximum sponse point on the plot depicting the lowest tensity condition. Accordingly, 10 000, 3 000 and approximately 1 000 Hz are identified as the best frequencies for turns 1, 2, and 3 respectively.[1] The frequency region of negativity widens with increasing stimulus level. This effect is the most dramatic in the basal turn, where the low frequency crossover from negative to positive response shifts from 6 000 Hz at 50 dB to approximately 700 Hz at 100 dB SPL. The second frequency region of interest is below the band of negativity. Here, at low frequencies, the response from all turns appears to be positive. Of course, as intensity increases and the negative band becomes wider, the positive band narrows. The third region of interest is encompassed by frequencies above the band of negative responses. For these high frequencies the DIF response component is small in comparison with the AVE potential. In contrast with the radical intensity dependence of the boundary between the positive and negative response regions, the high frequency boundary of the negative response changes only moderately with intensity. There is a general widening of the active region with increasing intensity, but it appears that beyond a certain frequency the response is always very small, no matter how high the stimulus intensity might be. Eight to nine thousand hertz is such a boundary for turn-two, while approximately 4 000–6 000 Hz is the limit for the active zone in turn-three.

The transition between zones is very sharp. Most of these plots are obtained with too few

[1] The absolute maximum of the DIF component in the first turn is achieved at approximately 15 000 Hz.

Fig. 10. Median SP versus stimulus frequency functions at several signal intensities from the second cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

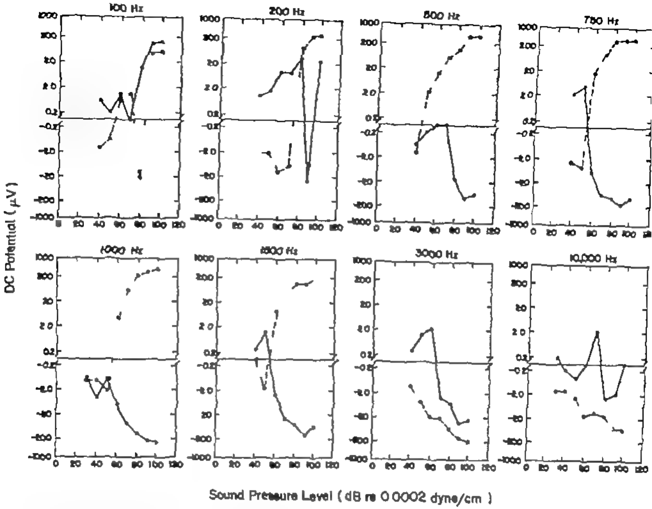

Fig 8 Median SP input–output functions at various frequencies from the third cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

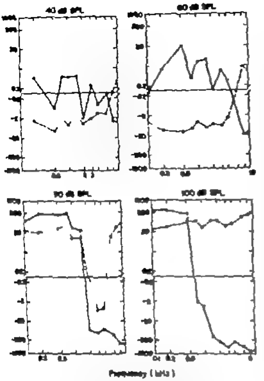
the local response is positive at the lowest frequencies in conformity with the results obtained from turns 1 and 2. The AVE response is negative at the low intensities at all frequencies, it becomes positive at higher intensities at low frequencies, and finally at high frequencies it is negative at all intensities. The DIF response becomes negligible at high frequencies, in the region of the best frequency (the exact frequency is missed in this series) it tends to be negative, while at that same frequency the AVE response is positive

All the contentions that were obtained from *input–output functions* can be put in even better perspective by examining some of the data in a different manner Instead of input–output functions, the results can be presented in the form of tuning curves, that is as SP versus frequency with intensity as the parameter In Figs. 9 10 and 11 such functions are shown for all three turns both for the DIF and the AVE components Only plots for a few intensities are shown, generally for one low one moderate and for one high SPL condition For the plots depicting the basal turn response an extra intensity level (90 dB) is also given for reasons that will become clear below

Let us first examine the DIF response component as the function of frequency The plots from all three turns clearly reveal the presence of different frequency zones within which the local response assumes a particular character There are three such zones, only two can be discerned in the first turn plots since these do not go



ig. 9. Median SP versus stimulus frequency functions t several signal intensities from the first cochlear turn. Plots are given for the DIF (●—) and AVE (○—○) components.

o sufficiently high frequencies. The zone of major importance is the one around the best frequency of the recording electrode. In this zone the local response is negative. The best frequency could be identified by the maximum response point on the plot depicting the lowest intensity condition. Accordingly, 10 000, 3 000 and approximately 1 000 Hz are identified as the best frequencies for turns 1, 2, and 3 respectively.[1] The frequency region of negativity widens with increasing stimulus level. This effect is the most dramatic in the basal turn, where the low frequency crossover from negative to positive response shifts from 8 000 Hz at 50 dB to approximately 700 Hz at 100 dB SPL. The second frequency region of interest is below the band of negativity. Here, at low frequencies, the response from all turns appears to be positive. Of course, as intensity increases and the negative band becomes wider, the positive band narrows. The third region of interest is encompassed by frequencies above the band of negative responses. For these high frequencies the DIF response component is small in comparison with the AVE potential. In contrast with the radical intensity dependence of the boundary between the positive and negative response regions, the high frequency boundary of the negative response changes only moderately with intensity. There is a general widening of the active region with increasing intensity, but it appears that beyond a certain frequency the response is always very small, no matter how high the stimulus intensity might be. Eight to nine thousand hertz is such a boundary for turn-two, while approximately 4 000–6 000 Hz is the limit for the active zone in turn-three.

The transition between zones is very sharp. Most of these plots are obtained with too few

[1] The absolute maximum of the DIF component in the first turn is achieved at approximately 15 000 Hz.

data points to appropriately delineate the sharpness of the transition, moreover the median plots tend to blur sharp changes. In order to illustrate the actual situation, the 60 dB condition in turn two is plotted in Fig. 12 with much finer frequency divisions for one particular animal. There we note that on the low frequency boundary the DIF response changes from $+10.0$ to $-3.6\ \mu V$ between 1 900 and 2 000 Hz, that is within 100 Hz.

The plots depicting the AVE response present a somewhat more complex picture than was seen for the DIF components. For the second and third turn responses three regions are again discriminable but in the first turn it appears that four frequency regions might be appropriately described. In the higher turns in the vicinity of the best frequency of the electrode location, the AVE response component is positive. As with the negative DIF component here again a band whose width is dependent upon the signal strength is seen: the more intense the stimulus, the wider the positive band about the best frequency. Again the extension of the band with increasing intensity is primarily toward the lower frequencies. Above the positive AVE response region this potential turns negative, this of course cannot be seen in the first turn response since data are not shown for sufficiently high frequencies. Below the best frequency positive region the AVE response turns negative. In turns two and three this low frequency region

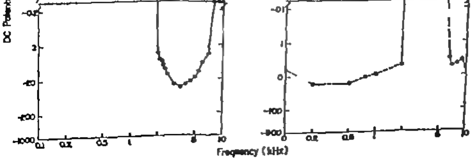

Fig 12 DIF and AVE SP components versus stimulus frequency functions for one representative animal, obtained from the second cochlear turn at a constant 60 dB SPL.

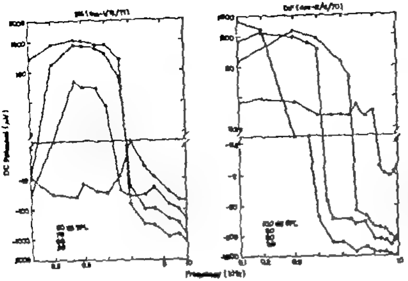

Fig. 13. Comparison between SP versus frequency functions obtained from scala media (SM) and the DIF component. Responses from the first cochlear turn are shown for representative individual animals. The parameter is sound pressure level.

of negativity is evident for only low and moderate signal levels because at high levels the positive region extends all the way down the measured frequency range. This negative region is also evident in the first turn AVE response, but here another complicating factor must be considered. Note that the negativity at low intensities extends down to 100 Hz, but as the intensity increases the response turns positive again. The higher the intensity the higher the frequency of this crossover. At 100 dB SPL the negative band is "filled in". It is probably worth emphasizing that the negative band is obliterated at high intensities by the simultaneous downward spread of the positive AVE component that is prominent in the best frequency region, and by the progressive upward spread of a low frequency positive region. This latter positivity is not evident in the higher turns, evidently a given frequency separation between the best frequency and its eliciting frequencies are required for the existence of this positivity.

Most of the plots presented thus far were obtained on the basis of median data. As a consequence the information contained in them represents the general trends seen in a fairly sizable number of animals. Individual animals depart from the general trend in the frequency and intensity regions where some component of the SP undergoes rapid changes. Since as we have seen complete polarity reversal can occur well within a 100 Hz frequency change (or for that matter within a 10 dB intensity change) it is not at all surprising that from animal to animal the exact crossover points do not remain at the same parameter values. It appears that even a slight difference in electrode location, to mention only one possible cause, could result in shifts of the crossover points between positive and negative SP components. The interaction of such individual differences is undoubtedly the cause of the jagged appearance of some of our median plots, particularly in the midfrequency and midintensity regions. For example in Fig. 4 (Turn-one input–output functions for DIF and AVE at 2 000 Hz) the average component vacillates rather sharply between 70 and 100 dB. This is clearly due to the differing crossover points among the animals that comprise the experimental sample.

The variety of plots shown above provide a quantitative description of the dependence of the SP as recorded in the perilymphatic scalae, upon the pertinent stimulus parameters: frequency and intensity. Because of our limited access to the cochlea the recordings are made from only three locations that correspond to the three lower turns of the inner ear. On the basis

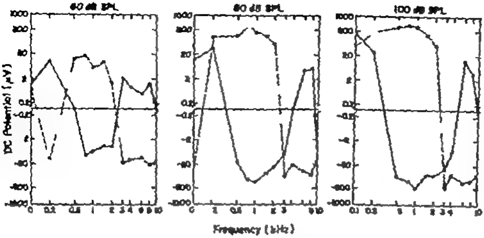

Fig 11 Median SP versus stimulus frequency functions at several signal intensities from the third cochlear turn. Plots are given for the DIF (●—●) and AVE (○—○) components.

data points to appropriately delineate the sharpness of the transition, moreover the median plots tend to blur sharp changes. In order to illustrate the actual situation the 60 dB condition in turn two is plotted in Fig 12 with much finer frequency divisions for one particular animal There we note that on the low frequency boundary the DIF response changes from +10 0 to −3 6 μV between 1 900 and 2 000 Hz, that is within 100 Hz.

The plots depicting the AVE response present a somewhat more complex picture than was seen for the DIF components. For the second and third turn responses three regions are again discriminable, but in the first turn it appears that four frequency regions might be appropriately described In the higher turns in the vicinity of the best frequency of the electrode location, the AVE response component is positive As with the negative DIF component here again a band whose width is dependent upon the signal strength is seen the more intense the stimulus, the wider the positive band about the best frequency Again the extension of the band with increasing intensity is primarily toward the lower frequencies. Above the positive AVE response region this potential turns negative, this of course cannot be seen in the first turn response since data are not shown for sufficiently high frequencies. Below the best frequency positive region the AVE response turns negative. In turns two and three this low frequency region

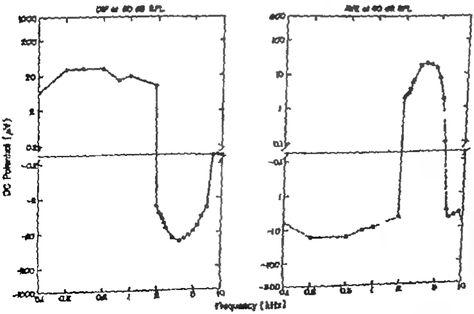

Fig 12 DIF and AVE SP components versus stimulus frequency functions for one representative animal, obtained from the second cochlear turn at a constant 60 dB SPL.

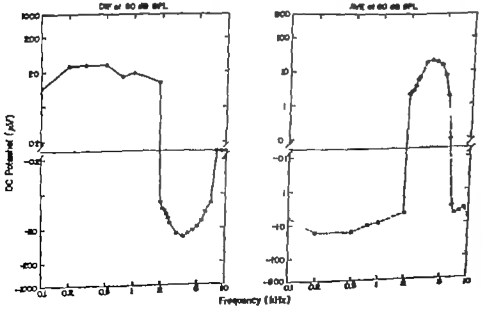

Fig 12 DIF and AVE SP components versus stimulus frequency functions for one representative animal, obtained from the second cochlear turn at a constant 60 dB SPL.

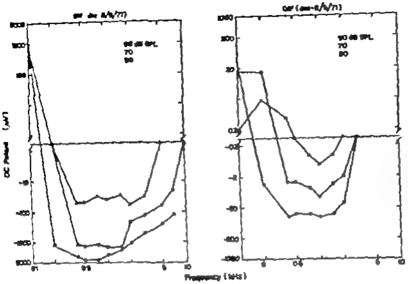

Fig. 15. Comparison between SP versus frequency functions obtained from scala media (SM) and for the DIF component. Responses from the third cochlear turn are shown for representative individual animals. The parameter is sound pressure level.

We have commented before that the general increase in the width of the negative band with signal strength in the DIF recording takes place toward the lower frequencies. We noted that characteristically the high frequency edges of the negative zones tend to coincide at most signal levels. This is clearly not the case in the SM recordings where the spread of negativity is quite regular and pronounced. Probably the most important differences are seen at low sound levels. In turns one and two the SM potential stays negative even at low frequencies below approximately 50 dB SPL. This behavior is in marked contrast with the DIF pattern which showed unmistakable positivity below the best frequency region at any intensity level. This low-intensity SM negativity that can be seen at all frequencies has eluded previous observers. Two similarities between SM and DIF recordings that are probably worth emphasizing are the tendency for peak SP magnitudes to decrease toward the apex, and the similarity between the magnitudes of the maximal SP− and SP+ at a given location. The first observation can be illustrated by noting (at a given SPL) the magnitude of the maximum SP either positive or negative, in the various turns. The maxima in turn-one are generally in excess of the maxima from the other two turns. The second observation naturally applies to relatively high SPL conditions only. There one is impressed by the fact that SP+ can be the same order of magnitude as SP− provided one records at sufficiently low frequencies. This fact has not been emphasized in the past. It is then probably inappropriate to consider only the SP− whether obtained from SM or from the perilymphatic scalae as a dominant response. The SP+ can be equally as significant, only it is prevalent in a different frequency zone.

DYNAMIC PROPERTIES OF THE SP

The general statement is often made that the SP waveform reflects the shape of the stimulus envelope. This is true to some extent and under some conditions, but there are numerous complicating factors. It is known for example that the waveform in SM is very different from that in say SV (Johnstone & Johnstone, 1966; Honrubia & Ward, 1969), it has also been noted that in particular frequency and intensity regions the shape of the SP bears little resemblance to the stimulus envelope, primarily because during the time course of the stimulus the SP reverses polarity (Konishi & Yasuno, 1963), a further obvious complication is the presence of the AP which obscures the onset of the response, and

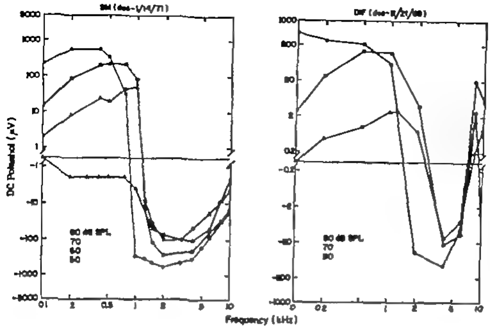

Fig 14 Comparison between SP versus frequency functions obtained from scala media (SM) and for the DIF component Responses from the second cochlear turn are shown for representative individual animals. The parameter is sound pressure level.

of the plots a number of conclusions have been drawn about the influence of stimulus parameters and recording location on the dc potential To investigate the relationship between SP in the perilymphatic scalae and that in SM we have repeated some of Honrubia & Ward s experiments We did this to assure similarity of procedure and overlapping parameter values, as well as to obtain data from the SM at low SPLs. Since Honrubia & Ward utilized direct oscilloscopic recording of the SP (not separated from CM) their signal to-noise limitations precluded the reliable recording of small dc potentials. Our averaging technique of course permits us to recover very small dc potentials from a high background of CM and physiological noise Moreover the procedure of evaluating the SP is different Honrubia & Ward measure the distance between the baseline and the center of the CM trace while we remove all ac components with the averaging process Thus the two sets of data can be expected to differ from one another

In Figs. 13 14 and 15 some of our SM recordings are presented These plots are for representative individual animals, for turns one two and three The graphs give the SP magnitude as the function of stimulus frequency with intensity as the parameter In each figure we have included for the sake of comparison the DIF–SP vs frequency plots of an individual animal The animal whose data are shown was chosen to be representative of our sample The only important difference between the two panels in a given figure is the ordinate scale Note that the logarithmic ordinate extends to $\pm 5\,000$ μV for the SM plots but only to the usual $\pm 1\,000$ μV for the DIF plots.

Even cursory inspection reveals that there is a great deal of similarity between the SM and the DIF plots. The most important feature of both, at least at high intensities, is the positive-to-negative transition with increasing frequency the pronounced negative zone around the best frequency and the diminishing response above the negative zone These overall details are quite familiar by now further discussion of them is not too profitable The consideration of some subtle differences between the SM and DIF plots, however is rather instructive

The width of the characteristic negative band is generally greater in the SM plots. This widening occurs without a very significant shift in the frequency of maximum negativity in other words the negative zone extends further toward both lower and higher frequencies. The extension, however is more pronounced and noticeable in the high frequency region, particularly as one observes the change in pattern with intensity

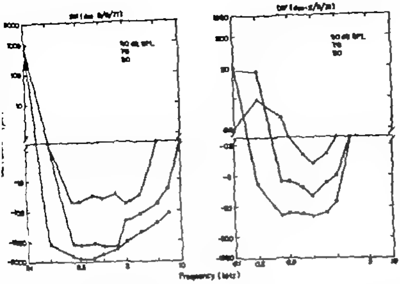

Fig. 15. Comparison between SP versus frequency functions obtained from scala media (SM) and for the DIF component. Responses from the third cochlear turn are shown for representative individual animals. The parameter is sound pressure level.

We have commented before that the general increase in the width of the negative band with signal strength in the DIF recording takes place toward the lower frequencies. We noted that characteristically the high frequency edges of the negative zones tend to coincide at most signal levels. This is clearly not the case in the SM recordings where the spread of negativity is quite regular and pronounced. Probably the most important differences are seen at low sound levels. In turns one and two the SM potential stays negative even at low frequencies below approximately 50 dB SPL. This behavior is in marked contrast with the DIF pattern which showed unmistakable positivity below the best frequency region at any intensity level. This low-intensity SM negativity that can be seen in all frequencies has eluded previous observers. Two similarities between SM and DIF recordings that are probably worth emphasizing are the tendency for peak SP magnitudes to decrease toward the apex, and the similarity between the magnitudes of the maximal SP− and SP+ at a given location. The first observation can be illustrated by noting (at a given SPL) the magnitude of the maximum SP either positive or negative in the various turns. It is then probably inappropriate to consider only the SP− whether obtained from SM or from the perilymphatic scalae as a dominant response. The SP+ can be equally as significant, only it is prevalent in a different frequency zone.

DYNAMIC PROPERTIES OF THE SP

The general statement is often made that the SP waveform reflects the shape of the stimulus envelope. This is true to some extent and under some conditions, but there are numerous complicating factors. It is known *for example that* the waveform in SM is very different from that in say SV (Johnstone & Johnstone, 1966; Honrubia & Ward, 1969); it has also been noted that in particular frequency and intensity regions the shape of the SP bears little resemblance to the stimulus envelope, primarily because during the time course of the stimulus the SP *reverses* polarity (Konishi & Yasuno, 1963); a further obvious complication is the presence of the AP which obscures the *onset of the* response, and

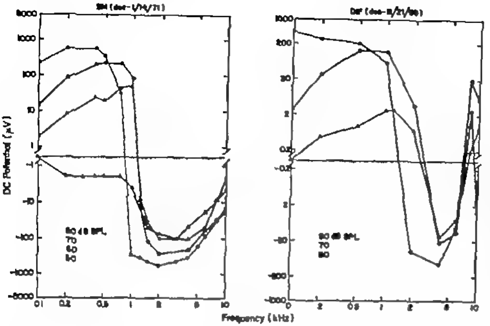

Fig 14 Comparison between SP versus frequency functions obtained from scala media (SM) and for the DIF component. Responses from the second cochlear turn are shown for representative individual animals. The parameter is sound pressure level.

of the plots a number of conclusions have been drawn about the influence of stimulus parameters and recording location on the dc potential To investigate the relationship between SP in the perilymphatic scalae and that in SM we have repeated some of Honrubia & Ward s experiments. We did this to assure similarity of procedure and overlapping parameter values, as well as to obtain data from the SM at low SPLs. Since Honrubia & Ward utilized direct oscilloscopic recording of the SP (not separated from CM) their signal to-noise limitations precluded the reliable recording of small dc potentials Our averaging technique of course permits us to recover very small dc potentials from a high background of CM and physiological noise Moreover the procedure of evaluating the SP is different Honrubia & Ward measure the distance between the baseline and the center of the CM trace while we remove all ac components with the averaging process Thus the two sets of data can be expected to differ from one another

In Figs. 13 14 and 15 some of our SM recordings are presented These plots are for representative individual animals, for turns one, two and three. The graphs give the SP magnitude as the function of stimulus frequency with intensity as the parameter In each figure we have included for the sake of comparison the DIF–SP vs. frequency plots of an individual animal The animal whose data are shown was chosen to be representative of our sample The only important difference between the two panels in a given figure is the ordinate scale Note that the logarithmic ordinate extends to $\pm 5\,000$ μV for the SM plots but only to the usual $\pm 1\,000$ μV for the DIF plots

Even cursory inspection reveals that there is a great deal of similarity between the SM and the DIF plots. The most important feature of both, at least at high intensities, is the positive-to-negative transition with increasing frequency the pronounced negative zone around the best frequency and the diminishing response above the negative zone These overall details are quite familiar by now further discussion of them is not too profitable. The consideration of some subtle differences between the SM and DIF plots, however is rather instructive

The width of the characteristic negative band is generally greater in the SM plots. This widening occurs without a very significant shift in the frequency of maximum negativity in other words the negative zone extends further toward both lower and higher frequencies. The extension, however is more pronounced and noticeable in the high frequency region, particularly as one observes the change in pattern with intensity

the presence of the afterpotential that confounds the cessation of the response (Stopp, 1969). The purpose of this section is to provide some general observation on the SP waveform for a variety of stimulus and recording conditions.

In Fig. 16 a series of averaged SP traces are given as recorded from the first cochlear turn of one particular animal with differential electrodes. Both the DIF and AVE components are shown in the two panels of the figure, in any given horizontal row the stimulus SPL is constant and frequency is changing, while in any column the frequency is constant and intensity is the variable. The data were actually collected by sweeping across frequency at a constant SPL level. Aside from the different dynamic properties of the DIF and AVE SP components, these traces in Fig. 16 reveal some other interesting differences between the two responses. The expected difference is of course their selective sensitivity to AP and CM. The onset whole nerve AP response (usually N_1 and N_2) is clearly visible in most AVE traces, and it is particularly evident at the higher stimulus frequencies. In a certain frequency region in addition to the onset AP a cessation response is also seen in the AVE traces (Kupperman, 1970). The AP responses are almost completely invisible in the DIF plots. In the latter however there are some components that are absent in the AVE traces. Specifically there is some CM response that is due to a combination of ringing in the acoustic system and onset transient, which does not average out as does the ordinary CM response to the carrier sinusoid. This CM is evident at the beginning of the response and immediately after the cessation of the stimulus. It is manifested as relatively slow oscillations. These are best seen at high frequencies and high intensities, they are present only in the DIF trace. A third interesting, not SP related, difference between DIF and AVE responses pertains to their differing registration of the slow afterpotential (Teas et al., 1962, Stopp, 1969).

Let us first see the change in the DIF waveform at high intensities as frequency is varied. Not SP-related events are ignored now that is the evident changes in ringing-response, and afterpotential are not being commented upon. At the lowest frequencies the DIF SP is clearly positive. At 500 Hz and 100 dB the waveform changes in that its later half begins to drop toward negative values. By 1 000 Hz the transition is complete and the final portion of the response is negative, above this the entire SP is negative, and it remains so for all higher frequencies. The waveform for all these high frequency high intensity DIF responses is quite square-shaped these are the classically recorded SP^- components. The appearance of all AVE responses at 100 dB SPL is quite uniform, these are all positive and quite square-shaped. The traces are more interesting at 90 dB SPL. The DIF component could be described exactly as we have done above with the exception that the positive-to-negative transition occurs at a higher frequency between 1 000 and 2 000 Hz. The AVE response encounters a double polarity reversal across frequency the first between 1 500 and 2 000 the second between 4 000 and 5 000 Hz. Neither of these reversals is characterized by a peculiar waveform change. The description of the 80 dB DIF traces is similar to the one given for the two higher intensities, the only exception is the shift in polarity reversal to the region of 3 000 Hz. The high frequency transition back to positive polarity occurs at 6 000 Hz, without any obvious change in waveform. The next three intensity levels for which traces are shown are 70 60 and 50 dB SPL. The DIF response at low frequencies is very small, generally positive, at these levels. The high frequency transition to negative polarity occurs between 4 000 and 6 000 Hz for all three, the emergence of the transition is first reflected by the later portion of the SP waveform. The AVE component is negative at low frequencies at the lower levels of stimulation, it turns positive between 9 000 and 10 000 Hz. It is interesting to note that at low intensities below approximately 1 000 Hz, where very little synchronized AP is evident, the waveform of the SP can be seen without the overlay of the neural response. In these conditions the AVE-SP appears to rise to its negative value relatively slowly

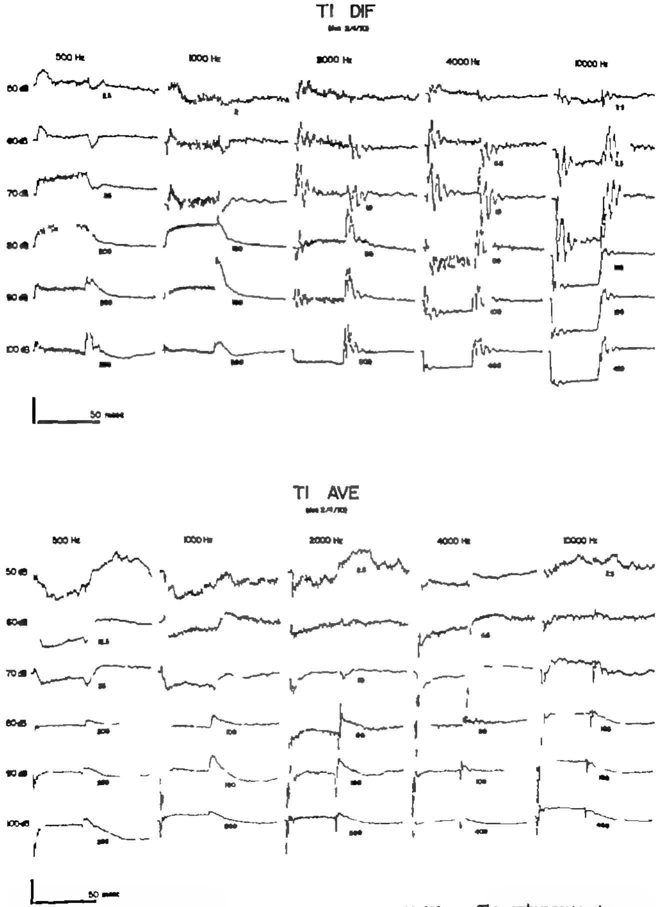

Fig 16 Averaged SP waveforms of the DIF and AVE components obtained from the first cochlear turn of one representative animal. In a given row the stimulus frequency is changing, while in a given column the stimulus intensity is changing. Stimulus duration = 40 msec, inter burst interval is 100 msec. The numbers next to the traces indicate the magnitude of the vertical calibration bar (in microvolts) that applies to the given trace. Positive potential is up in all traces.

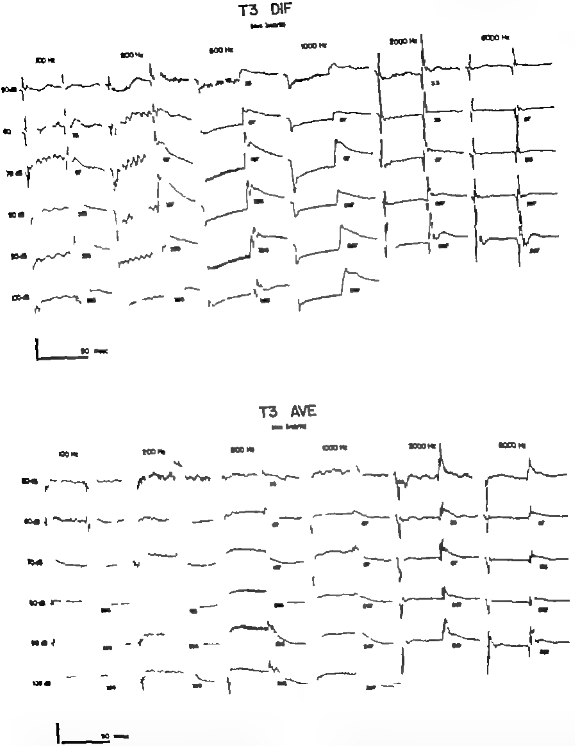

Fig. 18. Averaged SP waveforms of the DIF and AVE components obtained from the third cochlear turn of one representative animal. In a given row the stimulus frequency is changing, while in a given column the stimulus intensity is changing. Stimulus duration is 40 msec, inter burst interval is 100 msec. The numbers next to the traces indicate the magnitude of the vertical calibration bar (in microvolts) that applies to the given trace. Positive potential is up in all traces.

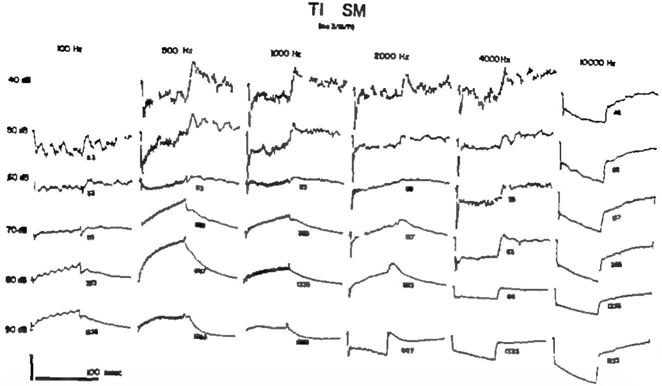

Fig 17 Averaged SP waveforms from the SM of the first cochlear turn of one representative animal. In a given row the stimulus frequency is changing, while in a given column the stimulus intensity is changing. Stimulus duration is between 60 and 80 msec and the interburst interval is 200 msec. The numbers next to the traces indicate the magnitude of the vertical calibration bar (in microvolts) that applies to the given trace. Positive potential is up in all traces.

In Fig. 17 a series of sample waveforms are shown for recordings from the scala media of the first cochlear turn. In analogy with Fig. 16 the responses are presented so that in any *horizontal row the stimulus intensity is constant* while in any vertical column the stimulus frequency is constant The entire array provides an overview of the frequency and intensity dependence of the SP from the SM of the first turn. The data were collected by keeping intensity constant and sweeping across frequency In the bottom row the high intensity 90 dB SPL, responses are depicted The SP is positive up to 1 000 Hz. The low frequency responses are slow potential changes, rapid components are notably absent Around 2 000 Hz the response is negative and reasonably square shaped As frequency increases the SP assumes its characteristic exponential form its magnitude increases during the duration of the signal This high frequency high intensity negative SP is actually composed of two response phases. Careful examination reveals that at both onset and cessation the smooth exponential change is preceded by a rapid response component The exponential portion begins considerably below the baseline, *most likely due to the presence of a rapid initial* SP response component The fast component is clearly seen at cessation. While the waveforms for the 80 dB condition are quite similar to the higher intensity pattern that was discussed above there are some important differences. The most striking difference is in the position of the polarity reversals and the attendant shifts in waveform. Compare for example the 2 000 Hz conditions at 80 and 90 dB While the response at 90 dB is negative and relatively square, it is positive at 80 dB and the waveform reveals the transitory nature of the SP As intensity is further lowered the negative-to-positive shift disappears and at 50 dB the response is negative at all frequencies At the lowest frequencies this negative response is quite square shaped there is a hint of a beginning transition between 500–2 000 Hz

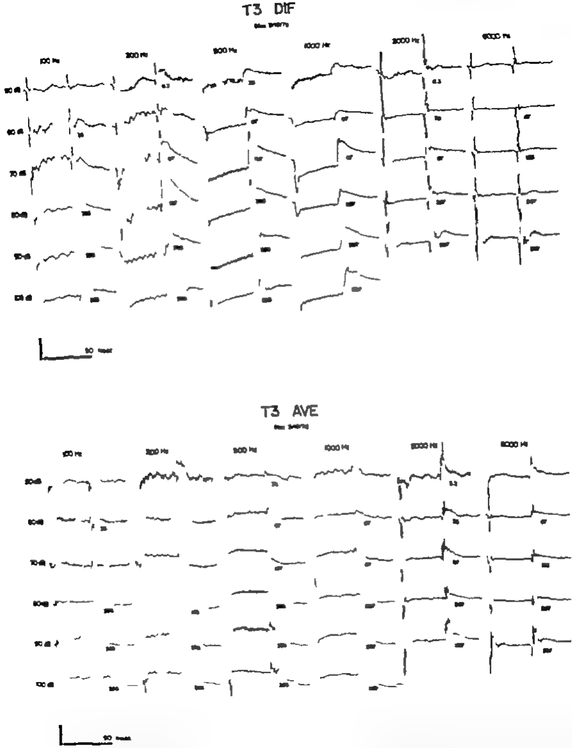

Fig. 11 Averaged SP waveforms of the DIF and AVE components obtained from the third cochlear turn of one representative animal. In given row the stimulus frequency is changing, while in given column the stimulus intensity is changing. Stimulus duration is 40 msec, inter burst interval is 100 msec. The numbers next to the trace indicate the magnitude of the vertical calibration bar (i microvolts) that applies to the given trace. Positive poten tial is up in all traces.

In a given row the stimulus frequency is changing, while in a given column the stimulus intensity is changing. Stimulus duration is 40 msec, inter burst interval is 100 msec. The numbers next to the traces indicate the magnitude of the vertical calibration bar (in microvolts) that applies to the given trace. Positive potential is up in all traces.

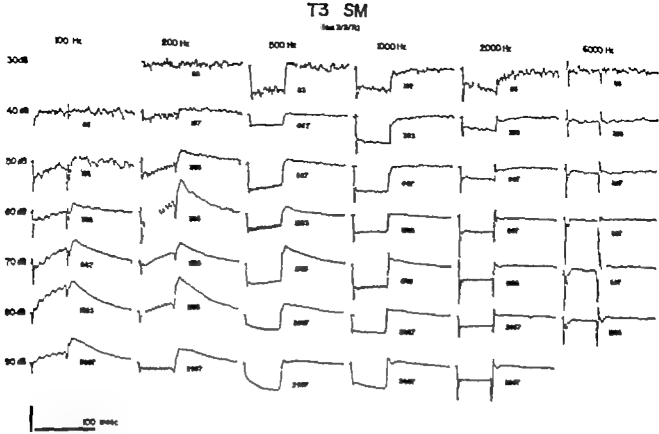

Fig 19 Averaged SP waveforms from the SM of the third cochlear turn of one representative animal. In a given row the stimulus frequency is changing, while in a given column the stimulus intensity is changing. Stimulus duration is approximately 60 msec and the interburst interval is 200 msec. The numbers next to the traces indicate the magnitude of the vertical calibration bar (in microvolts) that applies to the given trace. Positive potential is up in all traces.

in that the response seems to tend toward positive values, but the transition does not materialize and at the highest frequencies the waveforms have the already mentioned exponential, negative shape. It is instructive to remember the magnitude vs frequency functions plotted for turn-one SM data (Fig. 13) where we emphasized the loss of the positive low frequency response region at low intensities In the magnitude plot of Fig 13 the transitional zone where the response approached positive values was very clear it is interesting to note that this zone is also manifested in the appearance of the wave form as we have just noted

We will now consider the waveforms of SP responses from the more apical regions of the cochlea. Recordings from the third cochlear turn can serve as examples. DIF AVE, and SM responses are shown for representative animals, the first two sets in Fig. 18 while the latter set in Fig. 19 As before, in any given figure the stimulus intensity changes within a column and the frequency is variable within a row The low frequency DIF responses generally show a drift toward positive polarities during the onset of the response. This is quite clear for the 200 Hz low intensity conditions, where the SP starts out negative but turns positive by the end of the 40 msec ON-duration At higher stimulus levels for the 200 Hz, and at all levels at the 500 Hz condition the response stays negative during its entire duration, even though a pronounced decrease with time is seen. At increasing frequencies the responses become more square shaped and their magnitude is decreasing. Most AVE response waveforms are quite simple without characteristic transitions during the ON-period These responses are generally positive below 2 000 Hz, and negative at higher frequencies. As was seen in the first turn responses, the after

potentials show very interesting changes with stimulus parameter variations. As expected, the SM waveforms are considerably more complex than either the DIF or AVE ones. At the lowest stimulus levels the response, when discernible, is negative at all frequencies. We have emphasized this observation in connection with our first turn findings also. At 100 Hz the low level negativity gives way to a positive response as intensity is increased, the waveform however is quite complex in that the response rises and decays very slowly and that there are indications of fast onset and cessation transients superimposed on the slow wave. At 200 Hz the pattern is similar with the exception that at the highest SPL the response turns negative. It is worth noting here how this polarity reversal comes about. At this frequency one can clearly discern the presence of a fast response component at the onset and cessation of the response. This rapid component is in the negative direction but it is superimposed on a positive-going slow component. The net result of the superposition is that the overall response is positive between 60 and 80 dB, but that it turns negative at 90 dB. The responses are all negative in the best frequency region, that is for 500 and 1 000 Hz. At the highest intensities we see the familiar exponentially increasing SP at these frequencies. As in the first turn, the exponential changes are accompanied by the rapid on and off transients. Even at these frequencies there is an apparent remnant of the slow positive-going potential that we discussed in connection with the 200 Hz responses. The presence of this potential component can be discerned by considering the midintensity responses at 500 Hz. It is noticed that the response trace slants upward as time increases and that the baseline is approached slowly from above after the cessation of the stimulus. As intensity increases both of these effects decrease, first the actual response assumes its exponential shape, then the positive "afterpotential" diminishes. Actually if the 100 dB SPL condition would be shown here, the SP would approach the baseline very gradually from the negative direction. This waveform would strongly resemble the turn-one SM response at 10 kHz that was shown in Fig. 17. Above the best frequency region the third-turn SM waveforms are quite simple, there is apparently very little slow component in the response which is uniformly negative and gradually decreasing in size toward the higher intensities.

Discussion

The consideration that prompted this investigation was that a comprehensive study of an important class of cochlear phenomena, the summating potentials, was desirable but not available. As we have indicated in the introduction, during the past twenty years a considerable amount of information has been produced on the subject, but very little quantitative data have emerged. Particularly lacking was the description of the SP in all three cochlear scalae along the length of the basilar membrane for a wide variety of stimulus conditions. Our measurements of the potential gradient across the cochlear partition (DIF component), the common potential of the perilymphatic space at a given location (AVE component), and the potential inside the cochlear duct (SM component) were designed to provide a complete description of the dependence of these stimulus-related dc potentials upon stimulus parameters, and thus to pave the road toward the understanding of the *sources of origin and the significance of these* electrical events.

The most salient feature of the SP is seen to be its stringent dependence on stimulus parameters. At any given recording location in the cochlea the magnitude, the polarity and indeed the dynamic properties of the SP can easily be altered by moderate changes in stimulus frequency or intensity. Thus a complete description of the SP phenomenon is necessarily complex, particularly so considering our demonstration that the SP is not completely defined by the potential gradient across the cochlear partition but that another component (the AVE) is equally significant. Clearly the customary reliance on the high frequency high intensity summating potential response from the basal turn as an indicator of the behavior of the entire phenomenon can provide only limited, one-dimensional information. Thus the majority of investigations th assessed the dependence of the "summati potential" upon a host of experimental alter tions of cochlear equilibrium (i.e., pressu changes, anoxia, temperature, ionic balance, h cell damage, etc.) have actually described t behavior of the negative DIF component. O *results indicate that the positive DIF compone* or the positive AVE component can be just significant as the much investigated negati DIF response, only a different set of stimul and recording conditions are required for the elucidation. It might be appropriate at th point to briefly summarize our observations o the effect of stimulus parameters upon th various recordable SP components.

At any given electrode location there is a na row range of frequencies where the DIF com ponent is negative and the AVE component positive at *all* stimulus levels. The combinatio of recording conditions that would provide th *best example of this situation would invol* basal turn electrodes and a stimulus frequency 10 000 Hz. This combination would yield th cleanest example since only *local activity* woul have to be considered, inasmuch as the hig frequency stimulus would not spread mechanica excitation beyond the basal turn. Both DIF an AVE input–output functions are relativel simple in this situation, they show proportiona increase (approximately unity slope) in potential with stimulus level. The responses can be measured as low as 20 dB SPL, their magnitudes reach 700 1 000 μV at 100 dB. At a recording location that is far proximal from the peak of the traveling wave envelope the DIF component is positive at all intensities except possibly at the highest levels where it tends to turn negative. A basal turn electrode location together with a 200 Hz stimulus would be the prototype for this

condition. We might wish to note here that careful examination of the input–output function suggests that there might be a difference in the rate of growth ■ the positive DIF potential at low levels as opposed to that at high SPLs. The breakpoint is around 60 dB below that the slope is shallower above that it is probably in excess of unity The AVE component exhibits a very characteristic pattern under these recording conditions. It is initially negative, passes through a maximum, turns positive between 60–70 dB and then continues to grow The change from negative to positive of the AVE response, and the break in the growth of the DIF response tend to occur at similar intensities. These changes can probably best be appreciated with the perusal of the raw SV and ST plots. For example in Fig 3, in the 200 Hz plot one can clearly see how the two potentials start to depart from a similar course at 60 dB signaling a change in the DIF and AVE components.

In the situation when the traveling wa e maximum is far proximal from the recording electrodes we noted that the dominant potential is a relatively large negative AVE component The DIF response, when recordable, appears to be small in comparison with the AVE response and its input–output function tends to show unsystematic fluctuations. Under such conditions it is almost impossible to say with certainty whether or not the recorded DIF response is an artifact of inadequate cancellation of a common mode potential or if it is real but so small as to be impossible to assess reliably We tend to favor the first alternative The prototype condition for the demonstration of the negative AVE response is the one where recording takes place in the third cochlear turn and the stimulus is 10 000 Hz The AVE response can be recorded at very low stimulus levels, around 20–30 dB it grows at a rate of approximately 10 dB/20 dB (i e. it is proportional to the square-root of the stimulus strength), and it achieves a magnitude of 100–200 μV at 100 dB SPL.

It is apparent that both DIF and AVE components of the SP can be positive or *negative* depending on recording location and stimulus parameters. It is the relative dominance of one or more of these constituent responses that determines the overall behavior of the SP under a given condition. The examples above were so chosen as to isolate the constituents in a relatively pure form. Clearly as we alter the stimulus frequency the output of our first turn electrodes will change from the relatively simple negative DIF component at high frequencies to the relatively simple positive DIF component at the lowest frequencies. In the midfrequencies the experimental situation is more complex and the influence of stimulus intensity and frequency is strongly felt. Similarly when the recording electrodes are in the third turn, their output can run the gamut from the very simple high frequency AVE response that is always negative, to the more complex low and midfrequency responses that are strongly intensity and frequency dependent. In those situations where the change in a stimulus parameter does result in the polarity reversal of one of the SP components, the transition from one polarity to the other is generally quite precipitous. In other words, a frequency shift of less than a hundred Hertz, or an intensity change of a few decibels can move the response from a large positive to an equally large negative value or vice versa. For those stimulus conditions where the response is relatively "simple" in other words where one polarity prevails with wide changes in one of the parameters (i.e. turn-one high frequency response is insensitive to intensity changes or turn-one very high intensity response is insensitive to frequency changes) the response variability from animal to animal is very small. In contrast in the transition regions the variability is quite high

The scala media response is similar in character to the DIF component but its magnitude is approximately ten times as large as the corresponding DIF component. The characteristic negative band at a given electrode location extends to a considerably wider frequency range in the scala media recording than in the DIF response. One interesting difference between DIF and SM potentials is that at very low intensity

levels the SM response is negative at all frequencies In other words even for frequencies that have traveling wave maxima far distally from the electrode location the SM response is negative provided the intensity is low enough. In this respect the SM response appears to be also related to the AVE component which as we recall is negative for comparable conditions.

The waveforms of the various response components also reflect the experimental conditions that produce them Thus the waveform of a relatively "simple SP component is quite uncomplicated examples might be high frequency DIF responses from the first turn, or high frequency AVE responses from the third turn These waveforms are relatively square and not influenced by stimulus level In contrast, the waveforms that are produced in the transition zones often change polarity during the duration of the stimulus, reflecting the complexity of the recording situation The waveforms of the scala media potentials are more complex in appearance because under most conditions they are composed of a fast and a slow component, and in addition they too are subject to the added complexity in the transition regions.

The presence of a variety of apparently distinct components in the overall SP response would tend to indicate that a multiplicity of sources could interact in producing this response Thus one could begin with the premise that the positive and negative AVE and DIF responses all originate from different sources, or one could even go beyond this and assume that apparent slope changes in the input–output functions of some of the components signal the shift of that component from one mechanism of origin to another Just by inspecting the data of course one cannot resolve the problem of identifying sources and mechanisms of generation. Experiments specifically designed to selectively influence some of the suspected sources are required to ascertain the true composition of the response. At this juncture we can merely venture a few plausible suggestions about the origin of the various SP components.

The first important problem concerns the independence of the AVE and DIF components Let us for example consider the relatively pure DIF and AVE responses that are seen from the basal turn at high frequencies. Here we can deal with phenomena that are related to a hydromechanical disturbance that is confined to the vicinity of the electrodes, thus it is unlikely that the electrical responses would be confounded by remotely located active sources. The question to be answered is are the AVE and DIF components the result of the operation of two independent mechanisms, or are they the manifestations of the same process. In the latter case one would have to assume that the potential gradient would be the primary response, it would originate in the organ of Corti in some asymmetrical distortion process, while the common potential would have to be construed as a resultant of the first potential and that it would be produced by a simple electrical asymmetry between the scala tympani and scala vestibuli Such asymmetry is actually suggested by the circuit model proposed by Johnstone et al (1966) it can be shown (Dallos, 1972) that linear resistance change in the element that simulates the organ of Corti resistance in that model does yield an asymmetrical potential change at the two nodes that simulate the scala vestibuli and tympani The result of this is a possibility for a common-mode potential to appear in the two scalae

Since a large fraction of this communication is devoted to the description of the properties of the AVE component, it is appropriate to consider in some detail how such a common-mode potential could be produced merely as the result of asymmetries in cochlear electroanatomy The DIF and AVE components as we have said reflect the voltage gradient across the cochlear partition and the common mode potential of the two perilymphatic scalae The question naturally arises whether or not an actual change in the potential gradient would in any way influence the AVE potential and conversely whether an actual common potential shift of the cochlear cross section (both scalae) would be at all reflected in the DIF component. The answer is that under "ideal" recording condi

tions the DIF and AVE components are independent from one another. In other words if the recording situation is ideal then a change in the voltage gradient is manifested only in the DIF component, while a change in the common potential causes a change in only the AVE component. Ideal conditions mean perfectly balanced electrodes that are placed symmetrically across the cochlear partition, and whose amplifying chain possess the same gain. Such electrodes reflect the actual potential conditions in SV and ST without contributing their own bias. We must now emphasize a very crucial point. While in the case of ideal recording one can be confident that DIF and AVE reflect the actual gradient and common mode potential, the transition to the concept that the gradient reflects potential sources within the cochlear partition (between the electrodes) exclusively and the common potential reflects remote or extra-partition sources exclusively is not a straightforward one. An example will illuminate the problem. It has been the classic assumption (Tasaki et al. 1954) that a potential source within the organ of Corti would be seen in opposite phase in SV and ST. Thus Tasaki et al. identified the source of CM to be located in the region of the reticular lamina and Konishi & Yasuno (1963) identified the source of SP in the same region on the basis of phase inversion and polarity reversal respectively when recording electrodes were thrust through this area. Recent observations (Weiss et al. 1969, Dallos et al., 1971) indicate that such phase reversals do not obtain under all recording conditions. Specifically, in regions of the cochlea where the electroanatomy is complex, that is where resistance or reactance patterns are asymmetrical or where there is sufficient crosstalk between adjacent turns or regions, the CM phase across the partition can depart quite significantly from 180°. Such departures are also accompanied by magnitude differences. To explain this idea, let us expand the circuit diagram of Fig. 2*a* in the form shown in Fig. 2*b*. Here we still have only one source of potentials, E_D, assumed to be within the cochlear partition between the electrodes. The scala vestibuli and tympani recording points (V and T), however, have asymmetrical resistance paths to the source and to the common reference. The asymmetry is expressed by the multipliers k and n. In this case the following relationships hold

$$\mathrm{DIF} = E_V - E_T = \frac{(1+k)\,r E_D}{(1+k)\,r + (1+n)\,R},$$

$$\mathrm{AVE} = (E_V + E_T)/2 = \frac{\tfrac{1}{2}(k-1)\,r E_D}{(1+k)\,r + (1+n)\,R}$$

It is quite clear that unless $k = 1$ both the AVE and DIF components are influenced by the source. When $k = 1$ the AVE component vanishes. The greater k becomes, the more the AVE component approaches the magnitude of the DIF component. It is interesting to note that the asymmetry of the resistance path between the source and the nodes does not influence the DIF and AVE components in a selective manner.

A more general, even though still quite simplified, picture of the recording situation of interest can be studied with the aid of the circuit diagram shown in Fig. 2*c*. This diagram is a refinement of Fig. 2*b*: in it we assume the presence of two sources: one (E) is a source within the organ of Corti between the electrode tips, the other (E_A) is a remote, possibly extra-partition source. The two nodes, V and T, represent the points of measurement in scala vestibuli and tympani. It is simply assumed that the resistance paths from the nodes to the sources and to the reference point are unequal. The resistance differences are symbolized by the multipliers k, m, and n. In the desired optimal case the voltage difference between nodes V and T (DIF = $E - E_T$) would reflect E_D only, while the sum of these voltages [AVE = ($E + E$)/2] would reflect E only. It is a relatively straightforward matter to show that such conditions arise only if $k = m = n = 1$. Whenever there are asymmetries in the resistance paths, both E and E_A contribute to both the DIF and AVE measurements. The analysis of this circuit is straightforward. The solutions for DIF and AVE voltages are given as follows.

levels the SM response is negative at all frequencies. In other words even for frequencies that have traveling wave maxima far distally from the electrode location the SM response is negative provided the intensity is low enough In this respect the SM response appears to be also related to the AVE component, which as we recall is negative for comparable conditions.

The waveforms of the various response components also reflect the experimental conditions that produce them Thus the waveform of a relatively simple SP component is quite uncomplicated examples might be high frequency DIF responses from the first turn, or high frequency AVE responses from the third turn These waveforms are relatively square and not influenced by stimulus level In contrast, the waveforms that are produced in the transition zones often change polarity during the duration of the stimulus, reflecting the complexity of the recording situation The waveforms of the scala media potentials are more complex in appearance because under most conditions they are composed of a fast and a slow component and in addition they too are subject to the added complexity in the transition regions

The presence of a variety of apparently distinct components in the overall SP response would tend to indicate that a multiplicity of sources could interact in producing this response. Thus one could begin with the premise that the positive and negative AVE and DIF responses all originate from different sources or one could even go beyond this and assume that apparent slope changes in the input–output functions of some of the components signal the shift of that component from one mechanism of origin to another Just by inspecting the data of course one cannot resolve the problem of identifying sources and mechanisms of generation Experiments specifically designed to selectively influence some of the suspected sources are required to ascertain the true composition of the response. At this juncture we can merely venture a few plausible suggestions about the origin of the various SP components.

hydrodynamic activity is confined to the basal region of the cochlea, thus we do not have to contend with remote potential sources. We remember that in this situation there is a sizable AVE SP component of positive polarity that coexists with the negative DIF component. The magnitude ratio between these two potentials is of the order of 3 to 5, the DIF component being larger. These numbers are probably not significantly different from the predicted ratio. It is instructive to consider at this point the behavior of CM. In the situation that is of interest, namely when recording is in the basal turn and the stimulus is of high frequency, all evidence at hand indicates that the CM has virtually identical magnitude and opposite phase in ST and SV (Dallos et al., 1971). We have obtained considerable amount of data to compare the relative magnitudes of CM and SP, DIF and AVE components. One can simply state that in situations when the AVE CM component is 40–60 dB below the DIF CM component, the AVE and DIF SP components are of the same order of magnitude. In other words, the recordings indicate *virtually complete ac symmetry to go hand-in-hand with very significant dc asymmetry*. The former is manifested by the fact that the common-mode CM potential is only a hundredth or a thousandth of the CM gradient. The latter is of course indicated by the fact that the AVE and DIF SP components are commensurable. There are two possible explanations for the difference between symmetry properties in the cochlea for ac and dc signals. The first, and more obvious, explanation is that there are significant capacitive effects operating that would provide ac pathways between ST and SV and the potential source and also to ground, and would thus equalize the ac potentials without affecting dc imbalances. The other explanation is that the circuit asymmetries are not significant and that one must seek the source of generation of the AVE component in other cochlear processes. There is no conclusive experimental evidence either for or against the presence of strong capacitive effects operating in the outer scalae of the cochlea. Some considerations, however, drawn from the present experimental series, warn against accepting the presence of significant capacitive effects without actual experimental verification. Consider that if it is indeed capacitive equalization of the CM that yields virtually identical ST and SV potentials at high frequencies in turn-one, then one should be able to discern a gradual increase in CM disparity between these scalae as frequency is lowered and at very low frequencies the ST/SV microphonic ratio should approach that for SP. The latter is of the order of 1.5–5, that is the ST potential is larger by that factor. Even cursory study of CM versus frequency plots obtained from ST and SV reveals that there is a disparity between the potentials in the two scalae at low frequencies. The invariable result is, however, that the CM is *larger* in SV than in ST below approximately 2,000 Hz. The disparity is of the order of 1.6:1. We have stated previously (Dallos et al., 1971) that such differences (which are even more pronounced in the higher turns) are most likely the result of cross-talk between turns. It is thus possible that the circuit asymmetries are overshadowed by the opposite asymmetry provided by cross-conduction between turns. This would, however, require a very sizable amount of cross-conduction to completely reverse the effect. The resolution of this problem must await accurate reactance measurements in the cochlea. Lacking these, one cannot rule out the possibility that the AVE SP component is a manifestation of electroanatomical asymmetries of the inner ear.

All SP components, being dc responses to an ac stimulus, are the products of nonlinear distortion. One of the central problems in dealing with the SP is the determination of the nature and site of the involved nonlinear processes. A fair number of mechanisms have been suggested by various investigators; these have been confined to yield explanation of what we now recognize as the DIF component, and more particularly the negative DIF potential. Davis (1957) assumed a one-way bending of the cilia that would result from a longitudinal relative displacement between the reticular lamina and the tectorial

$$\mathrm{DIF} = \frac{rE_D}{D}[k(m+1)r\varrho + (k+1)m\varrho^2] + \frac{rE_A}{D}[(n+1)(k-m)\varrho R]$$

$$\mathrm{AVE} = \frac{rE_D}{2D}[(k-1)m\varrho^2 + k(m-1)r\varrho] + \frac{rE_A}{2D}[k(n+1)(r+\varrho)R + k(m+1)r\varrho]$$

where

$$D = r[(m+1)kr\varrho + (k+1)m\varrho^2] + R(n+1)[kr + (r+\varrho)m\varrho].$$

There are a few obvious relationships between DIF AVE, E_D, and E_A that one can see by inspecting these formulae In the case when $k=m$ the DIF potential does not depend on E_A but it is completely determined by E_D. When $R=0$ the DIF potential is of course identical to E_D. In order for the AVE potential to be independent of E_D, it is necessary that both k and m be equal to unity Since we would like to construe the DIF component as being primarily reflective of the source E_D, and conversely the AVE component as representative of E_A, it would be desirable to know how good such representations are Error coefficients can be expressed in the following manner

$$e_{\mathrm{DIF}} = \frac{E_D - \mathrm{DIF}}{E_D} = 1 - \frac{\mathrm{DIF}}{E_D}$$

$$\text{and } e_{\mathrm{AVE}} = \frac{E_A - \mathrm{AVE}}{E_A} = 1 - \frac{\mathrm{AVE}}{E_A}$$

One can substitute the expressions for DIF and AVE that were obtained above and after that formulae for the error coefficients are obtained in the following form

$$e_{\mathrm{DIF}} = A + B\frac{E_A}{E_D} \quad \text{and } e_{\mathrm{AVE}} = F\frac{E_D}{E_A} + G$$

In these formulae A B F and G are all functions of r R, ϱ and k m n Notice that in the case when, for example $E_A=0$ the error in the DIF component is constant and it is determined by the asymmetry of the circuit. If however E is not zero then in addition to the constant error we have an error component that increases with E_A/E_D. This means that the error in the DIF component increases without bound when E_A becomes much larger than E_D. The converse is of course also true the error in the AVE measurement becomes larger and larger as the output of the E_D source exceeds that of the E_A source These relationships can be expressed by saying that the most accurate measurement of the DIF component can be obtained in situations when E_A is small compared with E_D. In the recording situation when E_D is small in comparison with E_A the DIF component is prone to severely misrepresent the former source The converse is true for the relation between AVE and E_A

We see that as the result of asymmetries in the electrical cochlear network one can obtain significant DIF and AVE components from both intra (E_D) and extra partition sources (E_A) Let us concern ourselves with estimating the expected AVE component when the only source is E_D, the generator within the organ of Corti The equivalent electrical circuit of the cochlear cross section with resistance values obtained by Johnstone et al (1966) as shown in Fig. 2*d*, is used to serve as the basis of the computations. The solution of this simple circuit problem yields the following relations $E_V=0\,014E_D$ $E_T=-0\,05E_D$ $\mathrm{DIF}=0\,064E_D$ and $\mathrm{AVE}=-0\,018E_D$. Clearly the circuit analysis predicts that the scala tympani voltage (E_T) is considerably in excess of the scala vestibuli potential, and as a consequence of this asymmetry there is a sizable AVE component. The computations moreover predict that the AVE component is of opposite polarity from the DIF component The ratio of the magnitudes of the predicted DIF and AVE components is 3 56 These computations indicate that there is a very real possibility that the AVE component that we measure in the stimulus-related DC response is a simple manifestation of the organ of Corti source produced by the asymmetry of the cochlear network. A good analogue of the above computation is the situation when recording is made from the basal turn with high frequency stimulation. In this case all

hydrodynamic activity is confined to the basal region of the cochlea, thus we do not have to contend with remote potential sources. We remember that in this situation there is a sizable AVE SP component of positive polarity that coexist with the negative DIF component. The magnitude ratio between these two potentials is of the order of 3 to 5 the DIF component being larger These numbers are probably not significantly different from the predicted ratio It is instructive to consider at this point the behavior of CM In the situation that is of interest, namely when recording is in the basal turn and the stimulus is of high frequency all evidence at hand indicates that the CM has virtually identical magnitude and opposite phase in ST and SV (Dallos et al., 1971) We have obtained considerable amount of data to compare the relative magnitudes of CM and SP DIF and AVE components. One can simply state that in situations when the AVE CM component is 40–60 dB below the DIF CM component, the AVE and DIF SP components are of the same order of magnitude. In other words, the recordings indicate *virtually complete ac symmetry to go hand-in-hand with very significant dc asymmetry* The former is manifested by the fact that the common-mode CM potential is only a hundredth or a thousandth of the CM gradient. The latter is of course indicated by the fact that the AVE and DIF SP components are commensurable. There are two possible explanations for the difference between symmetry properties in the cochlea for ac and dc signals The first, and more obvious, explanation is that there are significant capacitive effects operating that would provide ac pathways between ST and SV and the potential source and also to ground, and would thus equalize the ac potentials without affecting dc imbalances The other explanation is that the circuit asymmetries are not significant and that one must seek the source of generation of the AVE component in other cochlear processes. There is no conclusive experimental evidence either for or against the presence of strong capacitive effects operating in the outer scalae of the cochlea Some considerations, however drawn from the present experimental series, warn against accepting the presence of significant capacitive effects without actual experimental verification. Consider that if it is indeed capacitive equalization of the CM that yields virtually identical ST and SV potentials at high frequencies in turn-one, then one should be able to discern a gradual increase in CM disparity between these scalae as frequency is lowered and at very low frequencies the ST/SV microphonic ratio should approach that for SP The latter is of the order of 1.5–5 that is the ST potential is larger by that factor Even cursory study of CM versus frequency plots obtained from ST and SV reveals that there is a disparity between the potentials in the two scalae at low frequencies The invariable result is, however that the CM is *larger* in SV than in ST below approximately 2 000 Hz. The disparity is of the order of 1.6 1 We have stated previously (Dallos et al., 1971) that such differences (which are even more pronounced in the higher turns) are most likely the result of cross-talk between turns. It is thus possible that the circuit asymmetries are overshadowed by the opposite asymmetry provided by cross-conduction between turns. This would, however require a very sizable amount of cross-conduction to completely reverse the effect. The resolution of this problem must await accurate reactance measurements in the cochlea. Lacking these, one cannot rule out the possibility that the AVE SP component is a manifestation of electroanatomical asymmetries of the inner ear

A fair number of mechanisms have been suggested by various investigators, these have been confined to yield explanation of what we now recognize as the DIF component, and more particularly the negative DIF potential. Davis (1957) assumed a one-way bending of the cilia that would result from a longitudinal relative displacement between the reticular lamina and the tectorial

$$\mathrm{DIF} = \frac{rE_D}{D}[\lambda(m+1)r\varrho + (\lambda+1)m\varrho^2] + \frac{rE_A}{D}[(n+1)(\lambda-m)\varrho R]$$

$$\mathrm{AVE} = \frac{rE_D}{2D}[(\lambda-1)m\varrho^2 + \lambda(m-1)r\varrho] + \frac{rE_A}{2D}[k(n+1)(r+\varrho)R + k(m+1)r\varrho]$$

where

$$D = r[(m+1)\lambda r\varrho + (\lambda+1)m\varrho^2] + R(n+1)[\lambda r + (r+\varrho)m\varrho]$$

There are a few obvious relationships between DIF AVE, E_D, and E_A that one can see by inspecting these formulae In the case when $\lambda = m$ the DIF potential does not depend on E_A but it is completely determined by E_D. When $R = 0$ the DIF potential is of course identical to E_D. In order for the AVE potential to be independent of E_D, it is necessary that both λ and m be equal to unity Since we would like to construe the DIF component as being primarily reflective of the source E_D, and conversely the AVE component as representative of E_A it would be desirable to know how good such representations are Error coefficients can be expressed in the following manner

$$e_{\mathrm{DIF}} = \frac{E_D - \mathrm{DIF}}{E_D} = 1 - \frac{\mathrm{DIF}}{E_D}$$

$$\text{and } e_{\mathrm{AVE}} = \frac{E_A - \mathrm{AVE}}{E_A} = 1 - \frac{\mathrm{AVE}}{E_A}$$

One can substitute the expressions for DIF and AVE that were obtained above, and after that formulae for the error coefficients are obtained in the following form

$$e_{\mathrm{DIF}} = A + B\frac{E_A}{E_D} \quad \text{and } e_{\mathrm{AVE}} = F\frac{E_D}{E_A} + G$$

In these formulae A B F and G are all functions of r R ϱ and λ m n Notice that in the case when for example $E_A = 0$ the error in the DIF component is constant and it is determined by the asymmetry of the circuit. If however E_A is not zero then in addition to the constant error we have an error component that increases with E_A/E_D. This means that the error in the DIF component increases without bound when E_A becomes much larger than E_D. The converse is of course also true, the error in the AVE measurement becomes larger and larger as the output of the E_D source exceeds that of the E_A source. These relationships can be expressed by saying that the most accurate measurement of the DIF component can be obtained in situations when E_A is small compared with E_D. In the recording situation when E_D is small in comparison with E_A the DIF component is prone to severely misrepresent the former source The converse is true for the relation between AVE and E_A

We see that as the result of asymmetries in the electrical cochlear network one can obtain significant DIF and AVE components from both intra (E_D) and extra partition sources (E_A). Let us concern ourselves with estimating the expected AVE component when the only source is E_D, the generator within the organ of Corti. The equivalent electrical circuit of the cochlear cross-section with resistance values obtained by Johnstone et al (1966) as shown in Fig. 2*d* is used to serve as the basis of the computations. The solution of this simple circuit problem yields the following relations $E_V = 0\,014E_D$ $E_T = -0\,05E_D$, $\mathrm{DIF} = 0\,064E_D$ and $\mathrm{AVE} = -0\,018E_D$. Clearly the circuit analysis predicts that the scala tympani voltage (E_T) is considerably in excess of the scala vestibuli potential and as a consequence of this asymmetry there is a sizable AVE component. The computations moreover predict that the AVE component is of opposite polarity from the DIF component The ratio of the magnitudes of the predicted DIF and AVE components is 3 56. These computations indicate that there is a very real possibility that the AVE component that we measure in the stimulus related DC response is a simple manifestation of the organ of Corti source, produced by the asymmetry of the cochlear network A good analogue of the above computation is the situation when recording is made from the basal turn with high frequency stimulation In this case all

merely a remote response in analogy with the similarly recorded AP. Indeed, this potential can be recorded in all regions of the cochlea that are distant from the maximum of the traveling wave envelope for a given stimulus: the response is strikingly present even far apically from the region of strongest excitation, i.e. in a segment where there is no excitation at all. This potential thus could be the reflection of distant activity: a passively conducted response. While this is a plausible concept, if adopted one must reconcile with it a few possibly contrary observations. First, we noted that the slope of the AVE⁻ input–output function is one-half, as opposed to the unity slope of the functions of those potentials whose remote reflection this AVE⁻ is supposed to be. Second, the relationship between the magnitudes of the AVE⁻ and the DIF⁻ components is such that the concept of assigning a mere remote response character to the AVE⁻ does not appear to be straightforward. To explain these ideas, in Fig. 20 simultaneously recorded first turn DIF and third turn AVE responses are shown at various intensity levels for four high frequencies, 6, 8, 10 and 12 kHz. Even the lowest of these frequencies generate a traveling wave that is completely extinguished far basally from the third turn electrode location. There are several interesting observations that can be made with the aid of these pairs of input–output functions. We note that indeed the slope of the AVE component is approximately one-half, and moreover the four AVE plots could virtually superimpose. In other words, over this 6 kHz frequency range, the third turn AVE response does not materially change with frequency. Highly significant changes do occur in the magnitude of the DIF components, however. As frequency increases this response becomes larger in the first turn. The relative magnitudes of the two components at various frequencies are very revealing. Note that at 12 kHz the DIF component is larger, except at the lowest intensity, while in contrast at 6 kHz the AVE component is larger, except at the highest intensity. If the AVE component would be a mere remote reflection of the DIF component then it is unlikely

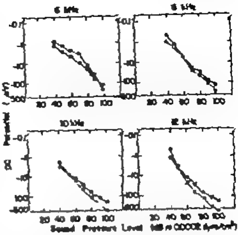

Fig. 20. Simultaneously recorded first turn DIF and third turn AVE SP responses from one guinea pig. Input–output functions are shown at four stimulus frequencies, 6, 8, 10 and 12 kHz. ●—● DIF ○—○ AVE.

that its magnitude would stay constant as the region of DIF-activity is constricted to ever diminishing segments in the basal portion of the cochlea (the frequency change corresponds to an approximately 2.5 mm movement of the traveling wave maximum). It would also be unlikely that its magnitude would be bigger than that of the DIF⁻ response that arises much closer to the point of maximum excitation, such as in the 6 kHz case. If we assume, however, that the AVE⁻ component is not simply a conducted remote response, but the actual counterpart of the AVE⁺ component, then these difficulties are somewhat alleviated. The one remaining problem that we have no immediate explanation for is the peculiar slope of the AVE⁻ input–output function, namely one-half. In the narrow region where the AVE⁺ component is positive at all intensities (in other words in the region where this component is maximum) its input–output function possesses unity slope. The question why the potential drop in the source and sink regions (that is the AVE⁺ and AVE⁻ components) would increase at different rates, can probably be explained by the nonlinear spread of the region of excitation with increasing intensity and thus by a nonlinear growth of current density. The hypothesized longitudinal cur-

membrane as the source of the SP− Tonndorf (1970) proposed two hydrodynamic mechanisms that could yield asymmetrical responses. Johnstone & Johnstone (1966) presumed that the relation between hair bending and basilar membrane displacement is nonlinear Their model could account for both SP− and SP+ Whitfield & Ross (1965) assumed that the basilar membrane displacement itself was asymmetrical Engebretson & Eldredge (1968) did not specify the site of the nonlinearity they only assumed that it is basically an asymmetrical saturating type one that can be expressed in terms of a polynomial transfer function Their analysis predicted close correlation between SP and other nonlinear cochlear processes, such as intermodulation distortion in the CM and the interference effect but could account for only the negative SP This scheme yielded an SP growth rate of 20 dB/10 dB SPL Our analysis of the electrical network model of cochlear electroanatomy that was proposed by Johnstone et al., (1966) clearly indicated that if it is assumed that linear displacements of the basilar membrane yield linear variations in the resistance of the organ of Corti then the resulting potential variations in the various scalae are distinctly nonlinear (Dallos, 1972) Others arrived at essentially similar conclusions (Strelioff 1971) The nonlinear CM potentials do have a dc component in this scheme, it is shown to rise with a slope of two with changing input intensity In studying cochlear distortion we have demonstrated that both harmonics and intermodulation components in the CM arise from a two-stage nonlinear process (Dallos et al 1969) At low sound levels the dominant nonlinearity is in the mechanoelectric conversion process of the hair cells, while at high sound levels a hydromechanical nonlinearity assumes dominance. It is reasonable to argue, based on the demonstration by Engebretson & Eldredge (1968) that there is a great deal of commonality among the various cochlear distortion processes, that at least some portion of the SP also might arise from the two major demonstrable nonlinearities hair cell transducer processes and hydrodynamic nonlinearities The demarcation between the two is probably controlled by t signal level It is then tempting to assume that t DIF SP response arises from the asymmetry the operating characteristic of the hair c transducer at low and moderate levels, and fro the rectification processes attendant to cochle hydrodynamics at high levels We have not some tendencies for two segments to exist in t input–output functions of the DIF componen with breakpoints at levels where the transiti between these two nonlinear processes usual occurs. It is quite probable that the source of t positive and negative DIF components is t same The difference between the two is th most likely the direction of shear on the cil is in different direction on the proximal (positi DIF) and distal (negative DIF) slopes of t traveling wave envelope. Békésy's (1953) obse vations on primary displacement directions o the two sides of the excitatory maximum suppo the possibility that inherently different shea patterns might exist on the two slopes of th traveling wave envelope.

It is notable that the overall slopes of bot the DIF− and DIF+ components input–outpu functions are approximately unity This is i contrast with the predictions that can be mad from the polynomial nonlinearity model o Engebretson & Eldredge or from the electro anatomy model that we have computed. Clearly the nonlinearity is more complex than wha these simple models envision.

While the tentative conclusion is that the posi tive and negative DIF components result fron the same nonlinear processes, the same migh be true for the two AVE components. One pos sibility is that a major portion of the AVE poten tials reflect voltage drops that result from longi tudinal current flow between strongly and weakly excited cochlear regions (Dallos et al., 1970) In this scheme the AVE+ potential would reflect the source region that would correspond to strong excitation, while AVE− would be associated with the sink of the longitudinal current flow that is with areas of weak or nonexisting excitation. Cursory examination of the AVE component might suggest that this potential is

scala media than in the perilymph. From the presence of both slow and fast response components one can surmise that the electrode "sees" the scala media SP through a circuit involving both resistive and capacitive elements. Apparently such capacitance is not involved to any significant measure in the registration of SP from the two outer scalae.

Our final consideration is directed toward establishing some relationships between CM, SP and the traveling wave pattern. To facilitate the discussion in Fig. 21 we are presenting a composite graph based on data from one particular animal. Included in the graph are CM and SP recordings from the third turn of the cochlea. The CM magnitude (obtained with differential electrode recording) at a constant 50 dB SPL, the DIF and AVE SP components at constant 50 dB SPL, all as functions of stimulus frequency are compared with the schematic tuning curve of basilar membrane displacement for the cochlear location where the electrodes are situated (approximately 14.5 mm from the stapes). From Békésy's frequency map (1944) one obtains a best frequency of 400 Hz, and the tuning curve is constructed by assuming its basal slope to be 6 dB/octave and its apical slope to be −100 dB/octave (Johnstone et al., 1970). We first note the good agreement between the frequency of the maximum CM and the maximum mechanical displacement. At the point of the maximum the phase of the CM is slightly in excess of 90° behind the sound, or what is equivalent, slightly more than 180° behind the CM in the basalmost part of the cochlea. In this particular case the maximum of the DIF⁻ response almost coincides with the maximum of the CM response; its frequency is about 300 Hz. It is striking that the DIF⁺ component peaks at a considerably higher frequency than the CM-traveling wave maximum. The difference is approximately one octave. This is a highly consistent finding. The AVE⁺ peak is more variable, in some animals it occurs at the same frequency as the DIF⁺ maximum, in others, as in the present case, it is at a lower frequency. The fact that the DIF⁺ component peaks at higher frequencies than the CM at a given location indicates that this potential has its maximum on the apical slope or even beyond the extent of the traveling wave envelope. We have shown that intermodulation components in the CM are similarly located with respect to the displacement pattern of the cochlear partition (Worthington & Dallos, 1971). These observations suggest that the nonlinearities that produce microphonic distortion at moderate sound levels and those responsible for the production of the DIF SP are related. It also appears that the positive DIF SP is best correlated with the point of maximum and the proximal slope of the traveling wave envelope, at least at low sound levels. As intensity increases, the negative DIF and positive AVE components expand much further basally and become the dominant responses over the entire spatial extent of the traveling wave.

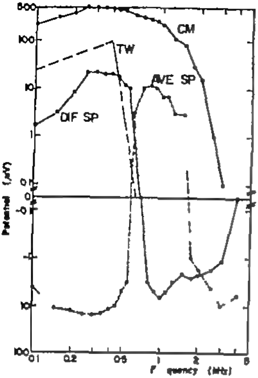

Fig 21 Various recordings obtained from third turn electrodes in one guinea pig. All these data are collected at a constant 50 dB SPL. The CM potential magnitude as recorded with differential electrodes is given in the top graph, the DIF and AVE SP components are also shown. The mechanical tuning curve (TW) for the cochlear location (14.5 mm) is schematized for comparison with the potential functions. The peak of the mechanical tuning curve is placed at 400 Hz in accordance with Békésy's cochlear map (1944) the low frequency slope is drawn as 6 dB/octave and the high frequency slope as −100 dB/octave

rent would be controlled by an active region in the vicinity of maximum excitation and it would flow into all inactive regions. This way the AVE⁺ would reflect the active region while AVE⁻ would prevail in all inactive regions Our study on cochlear damage (Dallos & Bredberg unpublished data 1970) indicated that there was excellent correlation between the integrity of the AVE⁺ producing active region and the normalcy of distant AVE potentials. For example in cases where there was almost complete damage of the third turn hair cell population and still a good first turn population existed the AVE potential recorded from the third turn in response to high frequency signals was virtually normal Conversely in this situation the low frequency low intensity negative segment of the first turn input-output function of the AVE potential was almost invariably missing One additional possibility that is worth mentioning is that some portion of the negative AVE response might reflect cochlear generator potentials In the original report on the SP phenomenon Davis and colleagues (1950) did assume that they were recording the post synaptic potential arising in the dendritic region of the auditory nerve A generator potential is certainly present in the auditory sense organ (Davis 1961) but it has not been experimentally identified as yet. It is possible that we do record this generator potential in those cases where at low signal intensity the AVE component is much greater than the DIF component, such as when recordings are made from the first turn at relatively low frequencies We have some preliminary evidence that indicates that these negative AVE potentials are indeed the manifestations of generator potentials. Thus for example these potentials disappear immediately after death while other SP components persist.

As we have noted there was a general similarity between SP patterns reflected by the DIF and SM components. Apparently both are primarily dependent on the potential gradient across the organ of Corti and are the manifestations of the same nonlinear processes. The differences between the DIF and SM patterns are probably attributable to the differing electrical circuit elements that are involved in the registration of these potentials at their respective recording sites One difference involved the wider spread of the SM component around its maximum. This is likely to reflect the better insulating properties of the cochlear duct than the perilymphatic channels The scala media is essentially a core conductor and potentials are expected to spread farther in it than in the more lossy scala vestibuli scala tympani complex Another related difference is the appearance of negative SP in the scala media at low intensities and at all frequencies. Apparently remote negative activity is conducted in the scala media with such small losses that it can overcome a generally small positive local response Finally the wave forms of the SP are radically different in the

scala media than in the perilymph. From the presence of both slow and fast response components one can surmise that the electrode "sees" the scala media SP through a circuit involving both resistive and capacitive elements. Apparently such capacitance is not involved to any significant measure in the registration of SP from the two outer scalae.

Our final consideration is directed toward establishing some relationships between CM, SP and the traveling wave pattern. To facilitate the discussion in Fig. 21 we are presenting a composite graph based on data from one particular animal. Included in the graph are CM and SP recordings from the third turn of the cochlea. The CM magnitude (obtained with differential electrode recording) at a constant 50 dB SPL, the DIF and AVE SP components at constant 50 dB SPL, all as functions of stimulus frequency are compared with the schematic tuning curve of basilar membrane displacement for the cochlear location where the electrodes are situated (approximately 14.5 mm from the stapes). From Békésy's frequency map (1944) one obtains a best frequency of 400 Hz, and the tuning curve is constructed by assuming its basal slope to be 6 dB octave and its apical slope to be 100 dB/octave (Johnstone et al 1970). We first note the good agreement between the frequency of the maximum CM and the maximum mechanical displacement. At the point of the maximum the phase of the CM is slightly in excess of 90° behind the sound, or what is equivalent, slightly more than 180° behind the CM in the basalmost part of the cochlea. In this particular case the maximum of the DIF$^+$ response almost coincides with the maximum of the CM response. Its frequency is about 300 Hz. It is striking that the DIF component peaks at a considerably higher frequency than the CM-traveling wave maximum. The difference is approximately one octave. This is a highly consistent finding. The AVE peak is more variable, in some animals it occurs at the same frequency as the DIF maximum, in others, as in the present case, it is at a lower frequency. The fact that the DIF component peaks at higher frequencies than the CM at a given location indicates that this potential has its maximum on the apical slope or even beyond the extent of the traveling wave envelope. We have shown that intermodulation components in the CM are similarly located with respect to the displacement pattern of the cochlear partition (Worthington & Dallos, 1971). These observations suggest that the nonlinearities that produce microphonic distortion at moderate sound levels and those responsible for the production of the DIF SP are related. It also appears that the positive DIF SP is best correlated with the point of maximum and the proximal slope of the traveling wave envelope, at least at low sound levels. As intensity increases, the negative DIF and positive AVE components expand much further basally and become the dominant responses over the entire spatial extent of the traveling wave.

Summary

An extensive study was performed to delineate the dependence of the stimulus related dc potentials of the cochlea (summating potential SP) on the parameters of the sound signal and on recording location Potentials were obtained from all three scalae of the first three turns of guinea pig cochleas. Data are presented from all these electrode locations and in addition the potentials in the perilymphatic space are evaluated in terms of the potential gradient (DIF) across the cochlear partition and the common mode potential (AVE) of the two perilymphatic scalae at a given location. Information is provided in terms of SP magnitude versus stimulus intensity functions with frequency as the parameter and also as SP magnitude versus frequency functions with intensity as the parameter Since a fairly large number of animals were used in this study and since consistent trends in the data were demonstrated, most results are given in terms of the median values of the available data. Aside from the SP magnitude data, representative SP waveforms are also shown for various stimulus conditions.

It was demonstrated that both SP magnitude and polarity as well as the waveform are very strongly dependent upon stimulus parameters and on the recording site This dependence however is orderly and predictable At a given recording location there is always a narrow frequency band within which the response assumes a characteristic polarity Within the band the scala media and the DIF responses are negative and the AVE component is positive at any sound pressure level At frequencies below the characteristic region the DIF response is positive and the AVE response is negative at least at low and moderate stimulus levels. As intensity increases, the negative DIF and positive AVE responses become dominant at lower and lower frequencies, and at very high sound levels at frequencies up to a cutoff point the DIF negative and the AVE is positive. At frequenc above the characteristic band the AVE respon is negative at all stimulus levels, while the D component becomes negligibly small. The obtained from scala media is very similar in behavior to that of the DIF response, but mu larger in magnitude. Other differences inclu the observation that in contrast with the D component, the scala media response is negat at low sound levels even at low frequencies. T chararacteristic negative band is generally wi for the scala media SP than for the DIF co ponent.

Comparisons with cochlear microphonic da and with the known properties of cochlear tra eling waves (Békésy 1944 Johnstone et a 1970) indicate that the peak negativity in t DIF and scala media responses occurs appro mately one octave above the maximum of t traveling wave envelope and the maximum the microphonic magnitude Thus these respo ses are maximal on the falling slope and in mediately distal to the spatial extent of t traveling wave In contrast, the positive DI component is more closely associated with t proximal slope and maximum of the travelir wave envelope. The positive AVE componen peaks between the traveling wave maximu and the negative DIF component maximun The negative AVE response is prevalent both o the proximal slope of the traveling wave an beyond the actual existence of this wave.

Some preliminary hypotheses about the natur and origin of the various SP components ar presented, but further work is required befor firm statements can be made The importan conclusions that arise from the present work in dicate that the SP is a multi-component response

that the various components all uniquely depend on stimulus parameters, and that under appropriate conditions any of the components can become dominant. Another important result pertains to the description of the AVE component and the demonstration that a very significant common-mode potential contributes to the SP response and thus that the SP under most conditions is of the same polarity on the two sides of the cochlear partition.

Summary

An extensive study was performed to delineate the dependence of the stimulus-related dc potentials of the cochlea (summating potential SP) on the parameters of the sound signal and on recording location. Potentials were obtained from all three scalae of the first three turns of guinea pig cochleas. Data are presented from all these electrode locations and in addition the potentials in the perilymphatic space are evaluated in terms of the potential gradient (DIF) across the cochlear partition and the common mode potential (AVE) of the two perilymphatic scalae at a given location. Information is provided in terms of SP magnitude versus stimulus intensity functions with frequency as the parameter and also as SP magnitude versus frequency functions with intensity as the parameter. Since a fairly large number of animals were used in this study and since consistent trends in the data were demonstrated most results are given in terms of the median values of the available data. Aside from the SP magnitude data, representative SP waveforms are also shown for various stimulus conditions.

It was demonstrated that both SP magnitude and polarity as well as the waveform are very strongly dependent upon stimulus parameters and on the recording site. This dependence, however is orderly and predictable. At a given recording location there is always a narrow frequency band within which the response assumes a characteristic polarity. Within the band the scala media and the DIF responses are negative and the AVE component is positive at any sound pressure level. At frequencies below the characteristic region the DIF response is positive and the AVE response is negative at least at low and moderate stimulus levels. As intensity increases, the negative DIF and positive AVE responses become dominant at lower and lower frequencies, and at very high sound levels at all frequencies up to a cutoff point the DIF is negative and the AVE is positive. At frequencies above the characteristic band the AVE response is negative at all stimulus levels, while the DIF component becomes negligibly small. The SP obtained from scala media is very similar in its behavior to that of the DIF response, but much larger in magnitude. Other differences include the observation that in contrast with the DIF component the scala media response is negative at low sound levels even at low frequencies. The charactеristic negative band is generally wider for the scala media SP than for the DIF component.

Comparisons with cochlear microphonic data and with the known properties of cochlear traveling waves (Békésy 1944 Johnstone et al., 1970) indicate that the peak negativity in the DIF and scala media responses occurs approximately one octave above the maximum of the traveling wave envelope and the maximum of the microphonic magnitude. Thus these responses are maximal on the falling slope and immediately distal to the spatial extent of the traveling wave. In contrast, the positive DIF component is more closely associated with the proximal slope and maximum of the traveling wave envelope. The positive AVE component peaks between the traveling wave maximum and the negative DIF component maximum. The negative AVE response is prevalent both on the proximal slope of the traveling wave and beyond the actual existence of this wave.

Some preliminary hypotheses about the nature and origin of the various SP components are presented, but further work is required before firm statements can be made. The important conclusions that arise from the present work indicate that the SP is a multi-component response,

that the various components all uniquely depend on stimulus parameters, and that under appropriate conditions any of the components can become dominant. Another important result pertains to the description of the AVE component and the demonstration that a very significant common-mode potential contributes to the SP response, and thus that the SP under most conditions is of the same polarity on the two sides of the cochlear partition.

Zusammenfassung

Eine umfassende Untersuchung wurde ausge führt um die Abhängigkeit der reizverbundenen dc Potentiale der Schnecken (summierendes Potential SP) von den Parametern des Schallsignals und der Lage der Registratur zu beschreiben Potentiale von den drei Abstufungen der ersten drei Wendungen in Meerschweinchenschnecken wurden erlangt Gezeigt wurden Werte all dieser Elektrodenlagen und ausserdem sind die Potentiale in dem perilymphatischen Raum berechnet in Form des potentiellen Ranges (*DIF*) über der Schneckenteilung und des gemein umstand Potentials (AVE) der zwei perilymphatischen Abstufungen in einer gegebenen Lage Information wird herbeigeführt in der Form von SP Umfang gegenüber Reizintensitätfunktionen wo Frequenz der Parameter ist und auch von SP Umfang gegenüber Frequenzfunktionen wo Intensität der Parameter ist Da eine ziemliche Anzahl Tiere in dieser Untersuchung studiert wurde und da übereinstimmende Tendenzen in den Werten demonstriert wurden sind die meisten Resultate als Mittelwerte der verfügbaren Werte angegeben worden Ausser den SP Umfangswerten werden auch typische SP Wellenformen für verschiedene Reizverhältnisse gezeigt

Es wurde demonstriert dass *SP* Umfang und Polarität sowie die Wellen form sehr von Reizparametern und der Lage der Registratur abhängen Allerdings ist diese Abhängigkeit regelmässig und voraussehbar In einer gegebenen Registraturlage gibt es immer ein schmales Frequenzband worin das Verhalten eine charakteristische Polarität annimmt In dem Band sind die Abstufungsmedia *und das* DIF Verhalten negativ und der AVE Komponent ist bei jeder Lautdruckhöhe positiv Bei Frequenzen unter der charakteristischen Region ist das *DIF Verhalten* positiv und das AVE Verhalten negativ jedenfalls bei niedrigen und mässigen Reizhohen. Mit Zunahme der Intensität dominieren die negativen DIF und positiven AVE Verhalten bei niedrigen und niedrigeren Frequenzen und bei sehr hohen Reizhohen bei allen Frequenzen bis zur Unterbrechung ist die DIF negativ und die AVE positiv Bei Frequenzen über dem charakteristischen Band ist das AVE Verhalten bei allen Reizhöhen *negativ während* der DIF Komponent unbemerkenswert klein wird Die SP die von den Abstufungsmedia erhalten wurde, ist dem Benehmen des DIF Verhalten sehr ähnlich jedoch viel grösser im Umfang Andere Unterschiede schliessen die Beobachtung ein dass im Gegensatz zu dem Komponenten das Verhalten der Abstufungsmedia bei niedrigen Schallhöhen negativ ist sogar bei niedrigen Frequenzen Das charakteristische negative Band ist im allgemeinen für die Abstufungsmedia SP weiter als für den DIF Komponenten

Vergleiche mit Schnecken mikrophonischen Data und mit den bekannten Eigenschaften der Schnecken wandernden Wellen (Bekesy 1944 Johnstone et al 1970) zeigen, dass die höchste Negativität in DIF und Abstufungsmedia Verhalten ungefähr eine Oktave über dem Maximum der wandernden Wellenhülle und dem Maximum der mikrophonischen *Hohe passiert So sind* diese Verhalten maximal auf der abfallenden Schräge und sofort distal zu dem räumlichen Ausmass der wandernden Welle Im Gegensatz ist der positiv DIF Komponent enger mit der proximal Schräge und dem Maximum der wandernden Wellenhülle verbunden Der positive AVE Komponent gipfelt zwischen dem Maximum der wandernden Welle und dem des negativen DIF Komponenten Das negative AVE Verhalten überweigt sowohl auf der unmittelbaren *Schräge als auch auf* der *wandernden* Welle und uber die Existenz der Welle hinaus.

Einige preliminäre Hypothesen über die Art

und den Ursprung mehrerer SP Komponenten und gezeigt, aber ein weiteres Studium ist notwendig bevor eine bestimmte Darlegung gegeben werden kann. Die wichtigen Folgen die von diesem Studium hervorgehen zeigen, dass der SP ein Multikomponentverhalten ist, dass die verschiedenen Komponenten einzigartig von Reizparameters abhängen, und dass unter bestimmten Umständen jeder Komponent dominieren kann. Ein weiteres wichtiges Ergebnis betrifft die Beschreibung des AVE Komponenten und die Demonstration, dass ein sehr bedeutendes gemein-umstand Potential zu dem SP Verhalten beiträgt, und daher dass das SP Potential unter den meisten Umständen die gleiche Polarität auf den zwei Seiten der Schneckenunterteilung hat.

Contents

This thesis is based mainly on experimental work presented in the following publications.

I BORG E. 1972. Excitability of the acoustic m stapedius and m tensor tympani reflexes in the nonanesthetized rabbit. *Acta Physiol Scand 85* 374

II BORG E. 1972 Regulation of middle ear sound transmission in the nonanesthetized rabbit. *Acta Physiol Scand 86* in press.

III BORG E. 1972. The dynamic properties of the acoustic middle ear reflex in nonanesthetized rabbits Quantitative aspects of a polysynaptic reflex system *Acta Physiol Scand 86* in press.

Reference to the above articles are indicated in the text by Roman numerals.

The aim of the present publication is

a) to review briefly current literature on middle ear muscle function and to point out some objectives for further investigation,

b) to discuss basic aspects of the use of frequency transfer functions in studies of reflex systems,

c) to present the main findings of the articles I II and III and to relate them to previous knowledge about middle ear muscle function and

d) to discuss specifically and generally the acoustic middle ear reflexes as a sensory-control mechanism in relation to the auditory system.

The following abbreviations are used

Introduction

A. CONTROL IN SENSORY SYSTEMS

1 General aspects.

Responses of sensory receptors and information flow in sensory nervous pathways are subjected to a variety of adjustments originating in, or mediated by the organism itself. In most sensory systems there are several efferent and feed-back control systems. Some have been extensively studied physiologically others are barely known to exist. Among the functionally studied control mechanisms the following can be mentioned: the gamma-efferents to the muscle spindle, the external eye muscles, the pupil, the efferent nerve fibers to the cochlea, to the vestibular organ, to the lateral line organ and some descending nerve tracts controlling transmission in sensory relay stations.

The main concerns of the functional analysis have been the activation of the control systems and their influence on the impulse flow in the ascending sensory pathways. Some of these control systems, such as the pupil, have been regarded for the most part to function reflexively as feed-back mechanisms. Others have been found to mediate complex control signals which to a great extent are of central origin, e.g. the gamma motor system and the efferents to the lateral line organ (Russell, 1971). In general, sensory control mechanisms have been studied only in lower animals, since most of them have not been accessible to experiments in man. The mechanisms of the external eye muscles and the pupil of the eye, however, have been investigated both in lower animals and in man. Recently the function of muscle spindles have been approached in human studies also (see e.g. Vallbo, 1971).

2 The auditory system.

In the auditory system of vertebrates a number of control mechanisms modify the ascending flow of information at different neural levels (for reviews, see Filogamo et al. 1967, Whitfield, 1968, Pfalz, 1969). Some of these systems have been established only anatomically (Held, 1893, Rasmussen, 1946, 1967, Borg, 1972 d) whereas others have been analysed functionally.

The afferent auditory activity is suppressed at the cochlear level as a result of electrical stimulation of the bundle of Rasmussen (the olivocochlear (OC) efferents; Galambos, 1956, Fex, 1962, Wiederhold, 1970). Single efferent nerve fibers have been found to be spontaneously active and also to fire in response to sound. There is thus evidence for a feed-back function of these fibers (Fex, 1962), but also for mediation of control from other brain centers. The OC pathway has been suggested to be of importance for discrimination of signals in noise (Dewson, 1968).

A facilitatory influence is exerted by the superior olive on activity in the ipsilateral cochlear nucleus as has been shown electro-physiologically and pharmacologically by Whitfield and co-workers (for review see Whitfield, 1968). In a series of experiments, Pfaltz and others (for review see Pfalz, 1969) analysed the inhibitory influence on the response of cochlear nucleus neurons initiated by stimulation of the contralateral cochlea. This binaural interaction was suggested to play a rôle in directional hearing.

In addition to these purely neural control mechanisms there are two others that act through striated muscles, (a) the movements of

A. CONTROL IN SENSORY SYSTEMS

1 General aspects

Responses of sensory receptors and information flow in sensory nervous pathways are subjected to a variety of adjustments originating in, or mediated by the organism itself. In most sensory systems there are several efferent and feed-back control systems. Some have been extensively studied physiologically others are barely known to exist. Among the functionally studied control mechanisms the following can be mentioned: the gamma-efferents to the muscle spindle, the external eye muscles, the pupil, the efferent nerve fibers to the cochlea, to the vestibular organ, to the lateral line organ and some descending nerve tracts controlling transmission in sensory relay stations.

The main concerns of the functional analysis have been the activation of the control systems and their influence on the impulse flow in the ascending sensory pathways. Some of these control systems, such as the pupil, have been regarded for the most part to function reflexively as feed-back mechanisms. Others have been found to mediate complex control signals which to a great extent are of central origin, e.g. the gamma motor system and the efferents to the lateral line organ (Russell, 1971). In general, sensory control mechanisms have been studied only in lower animals, since most of them have not been accessible to experiments in man. The mechanisms of the external eye muscles and the pupil of the eye, however, have been investigated both in lower animals and in man. Recently the function of muscle spindles have been approached in human studies also (see e.g. Vallbo, 1971).

2 The auditory system

In the auditory system of vertebrates a number of control mechanisms modify the ascending flow of information at different neural levels (for reviews, see Filogamo et al. 1967, Whitfield, 1968, Pfalz, 1969). Some of these systems have been established only anatomically (Held, 1893, Rasmussen, 1946, 1967, Borg, 1972 d) whereas others have been analysed functionally.

The afferent auditory activity is suppressed at the cochlear level as a result of electrical stimulation of the bundle of Rasmussen (the olivocochlear (OC) efferents; Galambos, 1956, Fex, 1962, Wiederhold, 1970). Single efferent nerve fibers have been found to be spontaneously active and also to fire in response to sound. There is thus evidence for a feed back function of these fibers (Fex, 1962), but also for mediation of control from other brain centers. The OC pathway has been suggested to be of importance for discrimination of signals in noise (Dewson, 1968).

A facilitatory influence is exerted by the superior olive on activity in the ipsilateral cochlear nucleus as has been shown electro-physiologically and pharmacologically by Whitfield and co-workers (for review, see Whitfield, 1968). In a series of experiments, Pfaltz and others (for review see Pfalz, 1969) analysed the inhibitory influence on the response of cochlear nucleus neurons initiated by stimulation of the contralateral cochlea. This binaural interaction was suggested to play a rôle in directional hearing.

In addition to these purely neural control mechanisms there are two others that act through striated muscles, (a) the movements of

the outer ear and (b) the contractions of the middle ear muscles, the m stapedius (St) and the m. tensor tympani (TT) The movements of the pinna have been found to have strong influence on the sound input to the cochlea in the bat (Wever & Vernon 1961) Recently the function of the pinna has been subjected to further analysis with respect to movements of the animal and the visual field (Schaefer et al., 1971) In the present study attention is focused on the other mechanical control system in the auditory periphery the middle ear muscles.

B MIDDLE EAR MUSCLES

1 General aspects

The two middle ear muscles, the St and the TT originate in the walls of the middle ear and insert on the ossicles. The St is innervated by the seventh cranial nerve and its contraction pulls the stapes in a posterior direction The TT is innervated by the fifth cranial nerve and its contraction pulls the eardrum medially The middle ear muscles are unique among the control mechanisms of the auditory system in as much as they are accessible for study in both animals and in man*) Quantitative information on the function of the middle ear muscle system in animals and/or in man can be gained from neuroanatomical, neurophysiological, behavioural and psychoacoustic experiments. It is reasonable to hope that such results can be combined successively to form a consistent conception about the function of the auditory input control in particular and the functional principles of sensory-control systems in general

Analysis of the middle ear muscle function gives rise to three main questions 1) What are adequate stimuli for muscle contractions? 2) To what extent is transmission of sound in the middle ear influenced by the muscles? and 3) What are the dynamic properties of this regulation?

*) Eventhough results were not obtained that could be ascribed to activity in the OC efferents, it now appears possible to also study the OC efferent functions in man (Picton et al 1971)

It is well established that nonacoustic as well as acoustic stimuli activate the middle ear muscles. Both in animals and in man the muscles contract during certain movements (Kato 1913 Carmel & Starr 1963 Salomon & Starr 1963 Simmons, 1964 a 1964 c *cf* Lüscher 1929) and during vocalization (Kato 1913 Carmel & Starr 1963 Simmons, 1964 a, 1964 c; Henson, 1965 Djupesland, 1967) Stimulation of the skin, especially on or near the outer ear and in the ear canal have also been shown to elicit contractions of the middle ear muscles (Kato, 1913 Klockhoff 1961) Quantitative information is lacking, however about the magnitude and consistency of the middle ear muscle activity evoked by these nonacoustic stimuli as well as the influence of the activity on sound transmission

2 Acoustic middle ear reflexes

Sound is the most consistently effective stimulus for middle ear muscle activation. The acoustic middle ear muscle reflexes have been recognized for nearly a century (Hensen 1878) yet their rôle in auditory perception is still far from well understood The reflex pathway as shown in studies on the rabbit (Borg, 1972 c) is basically a four neuron chain 1) primary auditory neuron 2) secondary neuron from the ventral cochlear nucleus to the medial superior olive, 3) interneuron to the facial motor nucleus (St) and the trigeminal motor nucleus (TT) 4) the motoneurons. In addition there is a shorter three-neuron pathway to the ipsilateral St as well as parallel multi-synaptic chains.

Sound having intensity well above hearing threshold and presented to one ear elicits contractions of the middle ear muscles in both ears In most animals both St and TT respond. In man whereas St is consistently activated as an acoustic reflex, TT contracts only as part of a startle reaction with acoustic or nonacoustic stimuli (Klockhoff 1961 Djupesland 1967) In a small percentage of individuals it is possible that TT contracts selectively in response to sound (Lidén et al 1970)

Several studies, both in man and animals,

have analyzed the functional properties of these muscles, chiefly with respect to excitability and influence on sound transmission in the middle ear. Since the intensity and frequency characteristics of natural sound are rapidly varying functions of time, an analysis of the dynamic properties of the middle ear reflexes is, however, essential for describing and understanding their rôle as regulators of the sound input to the inner ear.

a. Studies in man. The excitability of the middle ear muscles has been extensively investigated in man (for reviews, see Jepsen, 1963; Møller, 1972), as well as the influence on sound transmission (Pichler & Bornschein, 1957; Neergaard et al., 1963; Borg, 1968; Cancura, 1970) and the dynamic properties (Møller, 1962 a; Dallos, 1964; McRobert et al., 1968; Tietze, 1969). Most experiments have been performed on nonanesthetized subjects by measurement of changes in the acoustic impedance of the ear (Metz, 1946; Møller, 1961; Klockhoff, 1961; Zwislocki, 1963) or as changes in the air pressure in the outer ear canal (Terkildsen, 1957; Weiss et al., 1962; Holst et al., 1963; Mendelson, 1966). *In addition*, a more direct measure of the muscle activity has been obtained from recordings of the electromyograms of the St and TT usually in connection to ear operations (Perlman & Case, 1939; Fisch & Schulthess, 1963; Salomon & Starr, 1963; Djupesland, 1967). The regulation of sound transmission has been more difficult to determine. Temporal bone preparations (Neergaard et al., 1963; Cancura, 1970) have been used as well as subjects with temporary paralysis of the St (Borg, 1968).

In general, the results have shown that the St reflex threshold is about 80 dB above hearing threshold for pure tones (Jepsen, 1955; Møller, 1962 b) and somewhat lower for noise (Møller, 1962 a; McRobert et al., 1968; Flottorp et al., 1971; Peterson & Lidén, 1972).

The influence on sound transmission in man is limited roughly to the frequency range below 2.0 kHz (Borg, 1968; Cancura, 1970). The sound is attenuated almost exclusively. For low frequencies (below about 1.0 kHz), the attenuation increases at a fairly constant rate above reflex threshold: a 1.0 dB increase of sound intensity at the eardrum is attenuated to about 0.3 dB (Borg, 1968). Small improvements of sound transmission have been observed for sound frequencies at 2.0 to 3.0 kHz (Cancura, 1970).

The dynamic properties of the St reflex are intensity dependent but available estimates show that the middle ear reflex open-loop transfer function in man has a cut-off frequency (point of 3 dB attenuation) of 2 to 4 Hz and that the closed-loop system has a resonance peak at about 5 Hz (Møller, 1962 a).

The studies in man have been largely confined to a physiological analysis of the system and few psychoacoustic studies have analysed the rôle played by the middle ear reflexes in auditory perception (for a review, see Loeb, 1964).

In psychophysical *experiments* Smith (1943) and Reger (1960) showed that voluntary contractions of muscles in the middle ear increased hearing threshold for low frequency tones. The extent of these muscle contractions, both with regard to the number of muscles active (St, TT, m. tensor veli palatini: Walsh, 1967) and the degree of activation, as well as their relation to the acoustic reflexes is, however, unknown (Reger, 1960).

In patients with clinical signs of unilateral Bell's palsy with St paralysis Jepsen (1955) found that the loudness of high intensity tones with frequency below 1.0 kHz was often higher in the ear with paralysed St than in the normal ear and the timbre was different. Furthermore, a painful sensation associated with intense sound is commonly but not consistently found in persons with unilateral facial nerve damage and a presumed paralysis of the St (for a review, see Jepsen, 1955; Hansen, 1965). Perception of sound at hearing threshold was found not to be changed during St paralysis (Jepsen, 1955) or in any case, it is not altered more than 5 dB.

Patients with tendotomy of the St have been used to determine the rôle of St for speech discrimination in noise (Lidén et al., 1964), for

the outer ear and (b) the contractions of the middle ear muscles, the m stapedius (St) and the m. tensor tympani (TT) The movements of the pinna have been found to have strong influence on the sound input to the cochlea in the bat (Wever & Vernon, 1961) Recently the function of the pinna has been subjected to further analysis with respect to movements of the animal and the visual field (Schaefer et al. 1971) In the present study attention is focused on the other mechanical control system in the auditory periphery the middle ear muscles.

B MIDDLE EAR MUSCLES

1 General aspects

The two middle ear muscles, the St and the TT originate in the walls of the middle ear and insert on the ossicles. The St is innervated by the seventh cranial nerve and its contraction pulls the stapes in a posterior direction The TT is innervated by the fifth cranial nerve and its contraction pulls the eardrum medially The middle ear muscles are unique among the control mechanisms of the auditory system in as much as they are accessible for study in both animals and in man*) Quantitative information on the function of the middle ear muscle system in animals and/or in man can be gained from neuroanatomical neurophysiological, behavioural and psychoacoustic experiments. It is reasonable to hope that such results can be combined successively to form a consistent conception about the function of the auditory input control in particular and the functional principles of sensory-control systems in general

Analysis of the middle ear muscle function gives rise to three main questions 1) What are adequate stimuli for muscle contractions? 2) To what extent is transmission of sound in the middle ear influenced by the muscles? and 3) What are the dynamic properties of this regulation?

*) Eventhough results were not obtained that could be ascribed to activity in the OC efferents, it now appears possible to also study the OC efferent functions in man (Picton et al 1971)

It is well established that nonacoustic as well as acoustic stimuli activate the middle ear muscles. Both in animals and in man the muscles contract during certain movements (Kato, 1913 Carmel & Starr 1963 Salomon & Starr 1963 Simmons, 1964 a, 1964 c cf Lüscher 1929) and during vocalization (Kato, 1913 Carmel & Starr 1963 Simmons, 1964 a 1964 c, Henson, 1965 Djupesland, 1967) Stimulation of the skin, especially on or near the outer ear and in the ear canal have also been shown to elicit contractions of the middle ear muscles (Kato, 1913 Klockhoff, 1961) Quantitative information is lacking, however about the magnitude and consistency of the middle ear muscle activity evoked by these nonacoustic stimuli as well as the influence of the activity on sound transmission.

2 Acoustic middle ear reflexes

Sound is the most consistently effective stimulus for middle ear muscle activation. The acoustic middle ear muscle reflexes have been recognized for nearly a century (Hensen 1878) yet their rôle in auditory perception is still far from well understood The reflex pathway as shown in studies on the rabbit (Borg, 1972 c) is basically a four neuron chain 1) primary auditory neuron 2) secondary neuron from the ventral cochlear nucleus to the medial superior olive; 3) interneuron to the facial motor nucleus (St) and the trigeminal motor nucleus (TT) 4) the motoneurons. In addition there is a shorter three-neuron pathway to the ipsilateral St as well as parallel multi-synaptic chains.

Sound having intensity well above hearing threshold and presented to one ear elicits contractions of the middle ear muscles in both ears. In most animals both St and TT respond In man whereas St is consistently activated as an acoustic reflex, TT contracts only as part of a startle reaction with acoustic or nonacoustic stimuli (Klockhoff 1961 Djupesland 1967) In a small percentage of individuals it is possible that TT contracts selectively in response to sound (Lidén et al., 1970)

Several studies, both in man and animals,

tized animals have been presented. In most, chronically-implanted electrodes have been used to record cochlear potentials or the electromyogram of the middle ear muscles, chiefly in the cat and also in the bat and the guinea pig (Galambos & Rupert, 1959 Simmons, 1959 1960 a, 1960 b, 1963 1964 a, 1964 b, 1965 Carmel & Starr 1963 Baust & Berlucchi, 1964 Henson, 1965 Salomon 1966 Legouix & Foret, 1969). In a considerable proportion of these experiments the animals were restrained (Galambos & Rupert, 1959 Simmons, 1959 and others). The main concern of these studies has been the excitability of the reflexes, and the quantitative information on the regulation of sound transmission is sparse. The dynamic properties have only been studied on the basis of electromyograms (Salomon, 1966), which is of limited value for a description of the feed back function of the middle ear reflexes.

The most striking results of experiments with chronic-implanted electrodes were the low thresholds and variability of acoustic reflex responses, and the frequent nonacoustic activity of the muscles. The variability is to an important part related of fluctuation in state of wakefulness (Baust & Berlucchi, 1964), but other factors are also involved For example, reproducible reflex responses could only be obtained in cats after considerable effort, e g anesthetizing the animals after each experimental session (Simmons, 1964 b)

Furthermore, the variability has been probably due in part to difficulties in controlling stimulus conditions and in measuring sound pressure level In none of the studies in which chronic implants were used the sound pressure level was measured in the ear canal near the eardrum In some studies, foremost those where the animals were unrestrained, free-field stimulation was used (Galambos & Rupert, 1959 Carmel & Starr 1963 Starr 1964 Henson, 1965 Legouix & Foret, 1969) In this respect, it is well known that the pinna and the ear canal are important factors that influence the sound pressure level at the eardrum (Wiener & Ross, 1946 Worden et al 1964 Simmons & Beatty 1964 Wiener et al., 1965 Legouix & Foret, 1969)

The consequences of implanted electrodes in the middle ear have not been completely elucidated. It has not been shown that metallic implants are harmless to the function of the auditory periphery or the middle ear muscles (cf Simmons, 1967). To the contrary disturbances in middle ear muscle function seem probable: electrodes implanted in the St tendon of humans have been found to give rise to noise sensations (Salomon & Starr 1963). Influence of implants on excitable tissue of the ear are not unreasonable since it has been shown that metallic particles (e.g steel) implanted in the vitreous body of the eye dramatically influence the electrical activity of the retina (Knave, 1970). The effects on the electroretinogram were found to be dependent on the composition of the alloys used as implants. Electrodes implanted in the middle ear have been of steel as a rule but the composition has not been presented.

Thus, it appears desirable to investigate middle ear muscle function in nonanesthetized, unrestrained animals without the use of implants in the middle ear and with increased control of the stimulus conditions.

The use of different methods for studies of middle ear reflex function in man and animals serves to greatly complicate comparisons of data from animals and man. The higher reflex thresholds obtained by impedance measurements in man as compared to those obtained with chronically-implanted electrodes in cats have been attributed mainly to methodological shortcomings in the human experiments (Simmons, 1964 c). It would, indeed, have important consequences for our ideas about middle ear reflex function in man, and for further research, if the recent data from cats could be applied to humans in a quantitative way Methodological differences may be important, nontheless several differences between species have been revealed when identical methods have been applied to various animals, e g with respect to enzyme content of the middle ear muscles (Lotz et al., 1969), their response to succinyl-

temporary threshold shift after high intensity sound exposure (Mills & Lilly 1971) and for discrimination of double clicks (Wigand & Borucki, 1965) These authors have all reported differences between ears with and without St function.

One main difficulty with the forementioned psychoacoustic studies has been the determination of actual involvement of the middle ear muscles, e g the degree of St paralysis or voluntary activation The degree of St paralysis was in some experiments checked by recording the change, or lack of impedance change in the paralysed ear using contralateral sound stimulation in others only the involvement of the face muscles was observed It has been found in patients with Bell s palsy that the crossed response can be absent eventhough there is ipsilateral St activity on the affected side (Borg 1968 Borg unpublished) Thus, criteria used for St paralysis based on contralateral activation do not always suffice to exclude St activity in the ear used for psychoacoustic measurements Such shortcomings might account for some of the variability found

b Studies in animals Human experiments are necessary for psychoacoustic evaluation yet they are less well suited or even unacceptable for analysis of certain aspects of middle ear muscle function. Animal experiments can furthermore, often be performed under more well controlled experimental conditions than similar experiments in man The magnitude and mechanisms of the regulation of sound transmission and the open loop dynamic properties are most easily studied in animals. Animal experiments are indispensable for the analysis of the neuroanatomical basis of the reflex and its relation to other control mechanisms in the auditory system. The possible rôle of the middle ear reflexes in preventing or modifying fatigue and permanent acoustic trauma to the inner ear is another topic where animal experiments are appropriate.

Animal experiments have dealt chiefly with the basic properties of reflex excitability and influence of the reflexes on sound transmission through the middle ear Certain studies have also been concerned with acoustic trauma (Kato 1913 Taruya, 1953 Simmons, 1960 a Hilding, 1961) and the central reflex mechanisms (Hammerschlag, 1899 1901 Carmel & Starr 1963 Salomon 1966 Borg, 1972 c)

The results presented concerning reflex excitability and the influence on sound transmission have given a quantitatively inconsistent picture of these features. Factors such as narcosis (Borg & Møller 1967) decerebration or decortication (Carmel, 1963 Carmel & Starr 1963 Baust & Berlucchi 1964 Salomon, 1966) can be assumed to have influenced the results of acute experiments to an unknown degree.

Furthermore, studies of the regulation of sound transmission have regularly been performed with the acoustic bulla open and mostly with contralateral sound as the reflex stimulus (e g Wiggers, 1937 Bornschein & Krejci, 1952, Wever & Vernon 1955 1961 Møller 1965 Wigand 1965 Price, 1966) Openings in the wall of the bulla have been found recently to change the acoustic properties of the middle ear (Møller 1965 Tonndorf & Khanna 1967 Guinan & Peake, 1967) and also the effects of the middle ear muscles (Borg, 1972 a) The attenuation of a low frequency tone (800 Hz) by the middle ear muscles was found to be greater when the bulla was open than under normal conditions. There is also experimental evidence showing that the crossed reflexes are less excitable than the ipsilateral reflexes (Møller 1961 Borg & Møller 1968) in nonanesthetized animals and man. The difference is increased by anesthesia (Borg & Møller 1967) Thus, there are a number of technical details that may influence the magnitude of the recorded reflex responses and attenuation of sound transmission in acute experiments

The problems associated with narcosis have been realized for a long time. Thus, investigation of middle ear muscle functions in nonanesthetized animals without openings in the bulla and under conditions of ipsilateral sound stimulation became of primary interest

During the last ten to fifteen years an increasing number of experiments on nonanesthe-

tized animals have been presented. In most, chronically-implanted electrodes have been used to record cochlear potentials or the electromyogram of the middle ear muscles, chiefly in the cat and also in the bat and the guinea pig (Galambos & Rupert, 1959; Simmons, 1959, 1960 a, 1960 b, 1963, 1964 a, 1964 b, 1965; Carmel & Starr, 1963; Baust & Berlucchi, 1964; Henson, 1965; Salomon, 1966; Legouix & Foret, 1969). In a considerable proportion of these experiments the animals were restrained (Galambos & Rupert, 1959; Simmons, 1959 and others). The main concern of these studies has been the excitability of the reflexes, and the quantitative information on the regulation of sound transmission is sparse. The dynamic properties have only been studied on the basis of electromyograms (Salomon, 1966), which is of limited value for a description of the feed-back function of the middle ear reflexes.

The most striking results of experiments with chronic implanted electrodes were the low thresholds and variability of acoustic reflex responses, and the frequent nonacoustic activity of the muscles. The variability is to an important part related to fluctuation in state of wakefulness (Baust & Berlucchi, 1964), but other factors are also involved. For example, reproducible reflex responses could only be obtained in cats after considerable effort, *e.g.* anesthetizing the animals after each experimental session (Simmons, 1964 b).

Furthermore, the variability has been probably due in part to difficulties in controlling stimulus conditions and in measuring sound pressure level. In none of the studies in which chronic implants were used, the sound pressure level was measured in the ear canal near the eardrum. In some studies, foremost those where the animals were unrestrained, free-field stimulation was used (Galambos & Rupert, 1959; Carmel & Starr, 1963; Starr, 1964; Henson, 1965; Legouix & Foret, 1969). In this respect, it is well known that the pinna and the ear canal are important factors that influence the sound pressure level at the eardrum (Wiener & Ross, 1946; Worden et al., 1964; Simmons & Beatty, 1964; Wiener et al., 1965; Legouix & Foret, 1969).

The consequences of implanted electrodes in the middle ear have not been completely elucidated. It has not been shown that metallic implants are harmless to the function of the auditory periphery or the middle ear muscles (*cf.* Simmons, 1967). To the contrary, disturbances in middle ear muscle function seem probable: electrodes implanted in the St tendon of humans have been found to give rise to noise sensations (Salomon & Starr, 1963). Influence of implants on excitable tissue of the ear are not unreasonable since it has been shown that metallic particles (*e.g.* steel) implanted in the vitreous body of the eye dramatically influence the electrical activity of the retina (Knave, 1970). The effects on the electroretinogram were found to be dependent on the composition of the alloys used as implants. Electrodes implanted in the middle ear have been of steel as a rule but the composition has not been presented.

Thus, it appears desirable to investigate middle ear muscle function in nonanesthetized, unrestrained animals without the use of implants in the middle ear and with increased control of the stimulus conditions.

The use *of different methods for studies of* middle ear reflex function in man and animals *serves to* greatly complicate comparisons *of* data from animals and man. The higher reflex thresholds obtained by impedance measurements in man as compared to those obtained with chronically-implanted electrodes in cats have been attributed mainly to methodological shortcomings in the human *experiments* (Simmons, 1964 c). It would, indeed, have important consequences for our ideas about *middle ear reflex* function in man, and *for further research*, if the recent data *from* cats *could* be applied to humans in a quantitative way. Methodological *differences* may be important, nontheless several differences between species have been *revealed* when *identical* methods have been applied in various animals, *e.g.* with respect to enzyme content *of* the middle ear muscles (Lotz *et al.*, *1969*), their response to succinyl-

choline (Gisselson et al., 1957) their activity during chloralose anesthesia (Wersäll 1958) and the development of conditioned reflexes. Simmons et al. (1959) reported successful results from attempts to condition the middle ear muscles in the cat to light, whereas a similar procedure failed in man (Bates et al., 1970)

Analysis of the basic physiological properties of the acoustic middle ear reflexes in nonanesthetized unrestrained animals using methods identical to those used in man should provide a basis of evaluating results obtained with methods specific to animal experiments, e.g. experiments on effects of brain lesions, on protection from auditory trauma and on the physiological basis for use of the middle ear reflexes in clinical diagnosis.

For further reviews of the literature on the properties and function of the middle ear muscles, see e g Kato, 1913 Wever & Lawrence, 1954 Jepsen 1955 1963 Wersäll 1958 Cancura 1970 Møller 1972.

C SCOPE OF PRESENT STUDIES

In the previous review of current literature on the middle ear muscle physiology several problems appeared that demand further investigation. *One important task is a more detailed* quantitative investigation of the basic physiologic properties of the St and TT reflexes to sound in nonanesthetized, unrestrained animals.

The present study was undertaken in an attempt to analyse the acoustic middle ear reflexes quantitatively under well defined stimulus conditions in nonanesthetized unrestrained animals with respect to their excitability (I) influence on sound transmission (II) and dynamic properties (III) Methods were chosen to allow direct comparisons with data obtained in experiments on humans and to have minimal and controllable influence on the auditory periphery. The total reflex (St and TT in conjunction) as well as the isolated St and TT reflexes were investigated by means of ipsilateral and contralateral stimulation. The experiments were performed on chinchilla rabbits, animals found to be patient making anesthesia and restraining unnecessary

Three implications of these investigations may be mentioned a) to extend knowledge of the acoustic input control system b) the possibility of assessing species differences and c) general aspects on sensory system control mechanisms

The results showed that the excitability of the reflexes is significantly lower in the rabbit than in man. The regulation of sound transmission is about equally efficient as in man, only extended to higher frequencies in the rabbit. The dynamic properties could be described by second-order differential equations. It is *suggested on the basis of the results* obtained that the acoustic middle ear reflexes extend the dynamic range of the auditory system for intensity decrease making and add adaptation to the peripheral auditory system.

Notes on the methods

A RECORDING OF REFLEX RESPONSES (I II III)

The activity of the acoustic middle ear reflexes was recorded simultaneously in both ears as changes in the acoustic impedance of the ear at 800 Hz. A total of 78 rabbits of the small *chinchilla strain* were investigated. The animals *were sitting quietly in a box, open* at the top and they were not restrained. The measuring devices were hermetically sealed to the ear canals. Each of the two devices contained three electroacoustic transducers, one stimulus earphone one earphone for the 800 Hz measuring tone and one microphone. The measuring tone had an intensity at the eardrum of 65—70 dB

SPL (sound pressure level re. 0.0002 μb). The output of the microphone was balanced out electrically. Contractions of the middle ear muscles upset the balance and the resulting 800 Hz signal was recorded on a two-track tape recorder (Revox G35) together with a 7.4 kHz trigger signal synchronous with the stimulus. Analysis of the responses was performed at a later occasion from the signals which were rectified and lowpass-filtered (cut-off at 50 Hz, roll-off slope of 18 dB/octave) visualized on oscilloscope and recorded on film.

The amplitude of the signal representing the magnitude of the impedance change was measured at the end of the stimulus. These values were plotted as a function of sound pressure level after they had been converted to per cent of the maximal ipsilateral response of each ear. The stimulus-response curves described the steady-state properties of the reflex. Two curves for the ipsilateral, and two for the contralateral reflexes were obtained at each stimulus frequency. The stimuli were bursts of pure tones of 0.5 or 1.0 sec duration; the rise time to 90 per cent and the decay time to 10 per cent was in each case 2 msec. The frequencies 0.5, 1.45, 0, 4.0, 6.0, 8.0, 10.0 and 12.0 kHz were investigated in the intensity range from below reflex threshold to about 125 dB SPL. The sound pressures in the ear canal were measured in each experiment individually. This was accomplished with one of the transducers in the impedance measurement device which was connected to a probe terminating close to the eardrum. For the most part all of the frequencies were not investigated in each animal.

The total reflex (St and TT combined) was recorded in the first one to six experimental sessions on each animal. After surgical inactivation of one of the middle ear muscles, response of the remaining muscle was recorded. The properties of the isolated TT were obtained after paralysing the St. Since the St influences middle ear sound transmission, the properties of the isolated TT obtained were not identical to the TT properties under natural conditions, i.e. in conjunction with the St. The ipsilateral and the contralateral responses of the bilaterally isolated TT were found to differ only slightly (I), however. Thus, an adequate approximation to the properties of the TT under normal conditions was obtained from the crossed responses elicited by stimulation of the contralateral ear having both St and TT intact. In certain experiments, both muscles on one side were cut to make the study of the open-loop properties of the (contralateral) reflex possible.

The technique used for reflex recordings was originally developed for measurements on humans (Møller 1960, 1961) and was later shown applicable to nonanesthetized rabbits (Borg & Møller 1968). The method has been analysed with respect to validity and reliability. The steady-state amplitude of the impedance change was found to be proportional to the amplitude of the rectified, integrated EMG of the St (Borg, 1972 a) and thus can be assumed to be proportional to the contraction force of the muscle (Bigland & Lippold, 1954). The threshold for change in cochlear microphonics and in the impedance at 800 Hz was comparable to the threshold for the EMG of the St within 1 to 2 dB (Borg, 1972 a). The influence of the 800 Hz measuring tone was found to be negligible if it was kept below 75—80 dB SPL (Borg, 1972 b). The stability of the recordings during single experiments and the reproducibility from day to day was quantitatively analysed (Borg, 1972 b) by approximating a Gaussian distribution function to the stimulus-response curves of the reflex. The variability was found to be within a few dB: the standard deviation for the slope was 1.0 dB and for the position along the intensity axis it was 1.9 dB for reproducibility.

B. MEASUREMENT OF INFLUENCE ON SOUND TRANSMISSION (II)

Middle ear muscle contractions influence the sound transmission through the middle ear within certain ranges of frequency. The level of excitation in the cochlea to a certain stimulus will thus differ when the muscles are function-

choline (Gisselson et al., 1957) their activity during chloralose anesthesia (Wersäll, 1958) and the development of conditioned reflexes. Simmons et al (1959) reported successful results from attempts to condition the middle ear muscles *in the cat to light*, whereas a similar procedure failed in man (Bates et al 1970)

Analysis of the basic physiological properties of the acoustic middle ear reflexes in non anesthetized unrestrained animals using methods identical to those used in man should provide a basis of evaluating results obtained with methods specific to animal experiments, *e g* experiments on effects of brain lesions, on protection from auditory trauma and on the physiological basis for use of the middle ear reflexes in clinical diagnosis.

For further reviews of the literature on the properties and function of the middle ear muscles, see *e g* Kato 1913 Wever & Lawrence, 1954 Jepsen, 1955 1963 Wersäll 1958 Cancura 1970 Møller 1972

C. SCOPE OF PRESENT STUDIES

In the previous review of current literature on the middle ear muscle physiology several problems appeared that demand further investigation *One important task is a more detailed* quantitative investigation of the basic physiologic properties of the St and TT reflexes to sound in nonanesthetized, unrestrained animals

The present study was undertaken in an attempt to analyse the acoustic middle ear reflexes quantitatively under well defined stimulus conditions in nonanesthetized unrestrained animals with respect to their excitability (I) influence on sound transmission (II) and dynamic properties (III) *Methods* were chosen to allow direct comparisons with data obtained in experiments on humans and to have minimal and controllable influence on the auditory periphery The total reflex (St and TT in conjunction) as well as the isolated St and TT reflexes were investigated by means of ipsilateral and contralateral stimulation The experiments were performed on chinchilla rabbits, animals found to be patient making anesthesia and restraining unnecessary

Notes on the methods

A RECORDING OF REFLEX RESPONSES (I II III)

The activity of the acoustic middle ear reflexes was recorded simultaneously in both ears as changes in the acoustic impedance of the ear at 800 Hz. A total of 78 rabbits of the small chinchilla strain were investigated The animals were sitting quietly in a box, open at the top and they were not restrained The measuring devices were hermetically sealed to the ear canals. Each of the two devices contained three electroacoustic transducers, one stimulus ear phone, one earphone for the 800 Hz measuring tone and one microphone. The measuring tone had an intensity at the *eardrum of 65—70 dB*

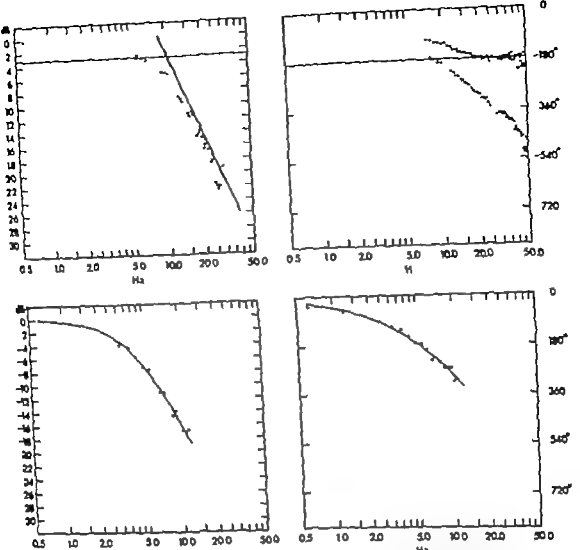

Fig. 1. *Left upper graph.* Amplitude characteristics of the open loop total reflex calculated on the basis of differentiated step response. Dots show calculated values, dB re highest value. Logarithmic frequency scale. Continuous lines show 3 dB attenuation (horizontal) and asymptote of high frequency slope (−12 dB/octave). *Right upper graph.* Phase characteristics of the open-loop total reflex calculated on the basis of an impulse response. Dots show total phase shift and triangles show phase shift when phase shift due to latency had been subtracted. Latency was calculated on the basis of slope of high frequency phase response. Straight line shows −180 degree phase shift. *Lower graph.* Frequency transfer function (Bode plot) of the ipsilateral open-loop total middle ear reflex, based on the crossed response and correction for difference between ipsilateral and contralateral reflex. The approximated second-order system model frequency transfer function is shown by continuous lines.

of frequency transfer functions listed above, the frequency transfer function can be obtained by using any signal which covers the frequency range of interest. If the input signal contains all frequencies in equal proportion, *i.e.* it has a flat spectrum, the procedure is simplified. In such a case the frequency transfer function of the system is equal to the Fourier transform of the output signal. Short impulses are signals that have a flat spectrum and are often used to determine the dynamic properties of systems. The same is true for steplike stimuli, but in this case the response (step response) has to be differentiated first in order to yield the transfer function by Fourier transformation of the output.

A major advantage of frequency-domain an-

ing normally as compared to when they are inactivated e.g. by surgery. Thus, if it is possible to measure quantitatively the level of excitation in the cochlea in a sufficiently reproducible way one would be able to calculate the influence of muscle contraction by comparing the responses of the cochlea during normal activity of the muscles and for inactivated muscles. The middle ear muscles provide such a reproducible measure of the afferent activity originating in the cochlea (Borg, 1972 b). A comparison of stimulus response curves of the crossed reflex elicited from the ear under investigation, before and after inactivation of the middle ear muscles on the investigated side, show directly the influence of the muscles in terms of change in sound transmission to the cochlea.

In the present experiments (II) as in a corresponding study in man (Borg, 1968) the crossed middle ear muscle reflex was used to measure changes of the afferent auditory activity. The ipsilateral reflex in the ear with intact muscles was used as a reference since it was not influenced by the operation. The shift in the curves was usually calculated on the basis of the average of stimulus-response curves obtained in several experimental sessions before and after inactivation of the middle ear muscles. The shift was a direct measure of the influence of the muscles on the transmission of the stimulus sound.

C. ANALYSIS OF DYNAMIC PROPERTIES (III)

Dynamic analysis of control systems has been thoroughly treated elsewhere (see e.g. d'Azzo & Houpis, 1966) and therefore only a few points will be discussed here.

The transfer function of a system is the ratio between the output and the input of the system. This (complex) ratio is usually measured by sinusoidal excitation throughout a large frequency range. The frequency transfer function specifies the ratio of the amplitude of the output to the input (in dB) and the difference in phase for sinusoidal signal as a function of frequency over a wide frequency range. It is usually visualized as a Bode plot (Figs. 1 and 3).

The usefulness of frequency transfer functions in dynamic analysis of biological systems is based mainly on three facts. First, the time course of any biological signal can be expressed as the sum of sinusoids of specified amplitudes and phase angles. The signal is thereby transformed from its original expression as a function of time (time-domain) to a function of the frequency of the sinusoidal components (frequency-domain) by means of a Fourier transform. Secondly, each frequency component can be treated separately in a number of calculations. Many times calculations are thereby greatly simplified. Thirdly, in any linear system the attenuation or amplification, and the shift in phase of each sinusoidal component of an input signal is independent of the other components present. Thus, if the frequency transfer function (the amplitude and phase characteristics) of a system is known, it can be used to determine the system output to an arbitrary input signal.

The dynamic properties of a system, expressed as a frequency transfer function, can thus be obtained by applying sinusoidal signals covering a wide frequency range to the system. Biological systems which are not linear can often be described similar to linear systems under certain restricted circumstances. Usually such systems behave like linear systems within small ranges of amplitude changes.

Frequency analysis with sinusoidal signals is the usual method for dynamic analysis of biological systems. However, it is not suitable when the system is nonlinear in such a way that the onset differs from the decay properties as e.g. in the middle ear reflexes (II). In addition the recordings take considerable time if a high degree of frequency resolution and statistical stability of the spectral estimates are wanted. If nonanesthetized, unrestrained subjects are used it is especially important not to use too time-consuming methods.

However, as follows from the basic properties

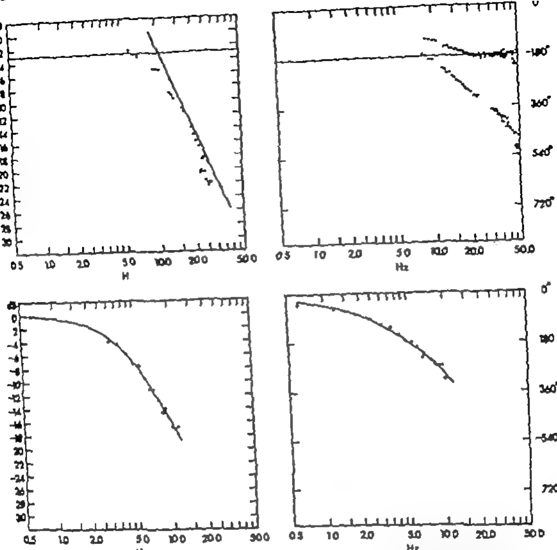

Fig. 1. Left upper graph. Amplitude characteristics of the open-loop total reflex calculated on the basis of differentiated step response. Dots show calculated values, dB re highest value. Logarithmic frequency scale. Continuous lines show 3 dB attenuation (horizontal) and asymptote of high frequency slope (—12 dB/octave). *Right upper graph.* Phase characteristics of the open-loop total reflex calculated on the basis of an impulse response. Dots show total phase shift and triangles show phase shift when phase shift due to latency had been subtracted. Latency was calculated on the basis of slope of high frequency phase response. Straight line shows —180 degree phase shift. *Lower graphs.* Frequency transfer function (Bode plot) of the ipsilateral open loop total middle ear reflex, based on the crossed response and correction for difference between ipsilateral and contralateral reflex. The approximated second-order system model frequency transfer function is shown by continuous lines.

of frequency transfer functions listed above, the frequency transfer function can be obtained by using any signal which covers the frequency range of interest. If the input signal contains all frequencies in equal proportion, *i.e.* it has a flat spectrum, the procedure is simplified. In such a case, the frequency transfer function of the system is equal to the Fourier transform of the output signal. Short impulses are signals that have a flat spectrum and are often used to determine the dynamic properties of systems. The same is true for steplike stimuli, but in this case the response (step response) has to be *differentiated* first in order to yield the transfer function by Fourier transformation of the output.

A major advantage of frequency-domain an-

alysis is that the response of the system to any signal whose characteristics (amplitude in dB and phase as a function of frequency) is known can be determined easily by adding (dB-values) the signal characteristics to the frequency transfer function of the system. It is also simple to compensate for any filtering that may occur in the measuring and analysis apparatus

In modelling such systems, the transfer function provides a convenient description of the properties of the system. Figure 1 (upper left graph) shows one example of an amplitude frequency transfer function of the open loop system of the total middle ear reflex. The dots show the amplitude (in dB re. the highest value, left) of the Fourier transformed differentiated response to a step stimulus. The frequency scale is logarithmic. It is seen that the amplitude decreases as the frequency increases, *i.e.* the system has a lowpass characteristic. The frequency where the amplitude has decreased to $1/\sqrt{2}$ of its maximal value (— 3 dB cut-off frequency) is often used to characterize the ability of the system to transmit fast variations in amplitude.

The slope of the amplitude transfer function at high frequencies is a measure of the complexity of the system. The number of integrations and differentiations that is made in the system can be estimated from this slope. It is basic for determining the order of the differential equation which can model the dynamic properties of the system. Each integration adds —6 dB/octave to the slope of the high frequency skirt. The negative slope of 12 dB/octave as shown in Fig. 1 (upper left graph) thus implies that a second-order differential equation can be expected to describe the acoustic middle ear reflex system adequately

The phase transfer function shows the time lag of the different Fourier components in relation to the input (dots of Fig. 1 upper right). When the phase lag of the open loop system is 180° (+ n 360°) there is risk of oscillation in the system. If the amplitude transfer function at this frequency is above 1 (0 dB) the system will oscillate with a continuously increasing amplitude (instability). Thus, it is important to know the characteristics of the system in this frequency region in order to predict its degree of stability

A certain amplitude characteristic implies a certain minimum phase change, *i.e.* there is a minimal value for phase shift at each frequency. If a system has a lowpass characteristic with a (negative) slope of 12 dB/octave, its minimum phase change is — 180° at high frequencies. In *a system with 18 dB/octave, the corresponding* minimum phase shift is — 270°. In most biological systems there is a latency time that adds to the minimum phase shift. This additional phase shift is proportional to the frequency. The dots of Fig. 1 (upper right graph) show the total phase shift of the middle ear reflex system. The triangles show the phase shift after subtracting the phase shift due to latency

The latency can either be determined directly from the time function responses, or from the slope of the phase transfer function at high frequency. Measurements in time-domain are uncertain for several reasons. Due to the gradual onset of the reflex response it is difficult to decide the point of departure from the baseline. Background noise adds variability and lag due to the filters used in the recording apparatus contributes to the latency. In the present study latency was determined from phase curve. The value obtained thereby becomes based on information in the response curve as a whole and corrections for filtering effects are easy

Figure 1 (lower graphs) shows the amplitude (dots, left graph) and phase (dots, right graph) values of the calculated Fourier transform based on differentiated step responses. The continuous line shows the transfer function of the model describing the properties of the reflex. The model is a second-order differential equation including a transport delay. Its Fourier transform is

$$G\ (j\omega) = \frac{Ke^{-T_1 j\omega}}{(j\omega + a)\,(j\omega + b)}$$

where K includes steady-state gain, T_1 represents the latency (sec), a and b are parameters (1/sec) and $j\omega$ is the complex frequency

In the present study (III) the *frequency-domain* transfer functions of the acoustic middle ear reflexes were determined as Fourier transforms of impulse responses and of differentiated step responses. The input signals were bursts of pure tones and the output signals were muscle contractions measured as impedance changes of the middle ear. The closed-loop responses (the situation where the reflexes influence the sound transmission to the cochlea) and the open-loop responses (the case where the reflexes do not influence the sound transmission) were determined for stimulation with pure tones of 0.5 and 0 kHz over a wide intensity range.

The dynamic properties of the middle ear reflex were found to be nonlinear with respect to amplitude. On the basis of earlier experiments (Borg, 1971 b) it was possible to derive conditions for which linear analysis methods could be used. It was concluded that the reflex functions as a different linear system for each reflex response amplitude. This assumption appears to be valid provided that the stimuli are rapidly changing in amplitude. During those circumstances, the reflex could be analysed using linear analysis methods. Furthermore, the onset and decay properties differed and therefore were analysed separately.

The technical details for determination of frequency transfer *functions* were presented in article III. Only a short summary is presented here. The signal representing the impedance change was sampled and converted to digital form in a computer (IBM 1800). The sampling started at the beginning of the stimulus as indicated by the trigger signal. The sampling rate (100 Hz) made it possible to determine the transfer function up to 50 Hz (Blackman & Tukey 1958).

The open-loop transfer functions were described by a mathematical model as a second-order system with transport delay. The parameters were determined by approximating the model transfer function to the values calculated *from experimental recordings* by using the least mean-square criterion for best fit. The parameters *of the model* were determined at several input amplitudes. The intensity dependence of the parameters was expressed by linear functions.

Outline of results

A. STEADY STATE PROPERTIES (I, II)

1. Excitability

The steady-state properties *of* the ipsilateral total middle ear muscle reflex in response to pure tone stimulation are summarized in Fig. .. The light shaded together with the heavily shaded area represent the region of tone frequency and sound pressure level for which response was obtained *from* the ipsilateral total middle ear reflex in awake, unrestrained rabbits. The threshold, defined as 10 % of the maximal obtainable impedance change, is indicated by the thin continuous line. The thin white line shows the threshold of the TT reflex when working together with the St, i.e. under normal conditions. The total reflex activity below this level consisted only of the St response. The difference in threshold between the St and TT reflexes was about 10 dB, independent of sound frequency. The excitability of the TT reflex was found to be influenced by *the St* activity *particularly at low sound frequency*. The isolated TT treshold *(St cut)* was *on the average* only 3 dB higher than the total reflex *threshold* at 0.5 kHz, but 10 dB at and above *2.0 kHz*.

The average threshold for the *ipsilateral* total *reflex and the St* reflex was 98 dB SPL at 0.5 *kHz* and decreased by about 12 dB/octave to *about 0 kHz*. Above 4.0 kHz it was on the average 70 dB SPL. The lowest threshold value *ever observed* was *44 dB SPL* (at 4.0 kHz). The

alysis is that the response of the system to any signal whose characteristics (amplitude in dB and phase as a function of frequency) is known can be determined easily by adding (dB-values) the signal characteristics to the frequency transfer function of the system. It is also simple to compensate for any filtering that may occur in the measuring and analysis apparatus.

In modelling such systems, the transfer function provides a convenient description of the properties of the system. Figure 1 (upper left graph) shows one example of an amplitude frequency transfer function of the open loop system of the total middle ear reflex. The dots show the amplitude (in dB re. the highest value, left) of the Fourier transformed differentiated response to a step stimulus. The frequency scale is logarithmic. It is seen that the amplitude decreases as the frequency increases, *i.e.* the system has a lowpass characteristic. The frequency where the amplitude has decreased to $1/\sqrt{2}$ of its maximal value (— 3 dB cut-off frequency) is often used to characterize the ability of the system to transmit fast variations in amplitude.

The slope of the amplitude transfer function at high frequencies is a measure of the complexity of the system. The number of integrations and differentiations that is made in the system can be estimated from this slope. It is basic for determining the order of the differential equation which can model the dynamic properties of the system. Each integration adds —6 dB/octave to the slope of the high frequency skirt. The negative slope of 12 dB/octave as shown in Fig. 1 (upper left graph) thus implies that a second-order differential equation can be expected to describe the acoustic middle ear reflex system adequately.

The phase transfer function shows the time lag of the different Fourier components in relation to the input (dots of Fig. 1 upper right). When the phase lag of the open loop system is 180° (+ n 360°) there is risk of oscillation in the system. If the amplitude transfer function at this frequency is above 1 (0 dB) the system will oscillate with a continuously increasing amplitude (instability). Thus, it is important to know the characteristics of the system in this frequency region in order to predict its degree of stability.

A certain amplitude characteristic implies a certain minimum phase change, *i.e.* there is a minimal value for phase shift at each frequency. If a system has a lowpass characteristic with a (negative) slope of 12 dB/octave, its minimum phase change is — 180° at high frequencies. In a system with 18 dB/octave, the corresponding minimum phase shift is — 270°. In most biological systems there is a latency time that adds to the minimum phase shift. This additional phase shift is proportional to the frequency. The dots of Fig. 1 (upper right graph) show the total phase shift of the middle ear reflex system. The triangles show the phase shift after subtracting the phase shift due to latency.

The latency can either be determined directly from the time function responses, or from the slope of the phase transfer function at high frequency. Measurements in time-domain are uncertain for several reasons. Due to the gradual onset of the reflex response it is difficult to decide the point of departure from the baseline. Outline of results

A STEADY STATE PROPERTIES (I, II)

1 Excitability

The steady-state properties of the ipsilateral total middle ear muscle reflex in response to pure tone stimulation are summarized in Fig 2. The light shaded together with the *heavily* shaded area represent the region of tone frequency and sound pressure level for which response was obtained from the ipsilateral total middle ear reflex in awake, unrestrained rabbits. The threshold, defined as 10 % of the maximal obtainable impedance change, is indicated by the thin continuous line The thin *white line* shows the threshold of the TT *reflex* when working together with the St, *i e* under normal conditions The total reflex activity below this level consisted only of the St response. The *difference* in threshold between the St and TT reflexes was about 10 dB, independent of sound *frequency* The excitability of the TT reflex was *found to be* influenced by the St activity *particularly at low sound* frequency The isolated TT treshold (St cut) was on the average only 3 dB higher than the *total reflex threshold* at 0.5 kHz, but 10 dB at and above 2.0 kHz.

The average threshold for the *ipsilateral total* reflex and the St reflex was 98 dB SPL at 0 5 kHz and decreased by about 12 dB/octave to *about* 0 kHz. Above 4.0 kHz it was on the average 70 dB SPL. The lowest threshold value *ever observed was 44 dB SPL* (at 4 0 kHz). The

alysis is that the response of the system to any signal whose characteristics (amplitude in dB and phase as a function of frequency) is known can be determined easily by adding (dB values) the signal characteristics to the frequency transfer function of the system. It is also simple to compensate for any filtering that may occur in the measuring and analysis apparatus.

In modelling such systems, the transfer function provides a convenient description of the properties of the system. Figure 1 (upper left graph) shows one example of an amplitude frequency transfer function of the open loop system of the total middle ear reflex. The dots show the amplitude (in dB re. the highest value, left) of the Fourier transformed differentiated response to a step stimulus. The frequency scale is logarithmic. It is seen that the amplitude decreases as the frequency increases, *i.e.* the system has a lowpass characteristic. The frequency where the amplitude has decreased to $1/\sqrt{2}$ of its maximal value (— 3 dB cut-off frequency) is often used to characterize the ability of the system to transmit fast variations in amplitude.

The slope of the amplitude transfer function at high frequencies is a measure of the complexity of the system. The number of integrations and differentiations that is made in the system can be estimated from this slope. It is basic for determining the order of the differential equation which can model the dynamic properties of the system. Each integration adds —6 dB/octave to the slope of the high frequency skirt. The negative slope of 12 dB/octave as shown in Fig. 1 (upper left graph) thus implies that a second-order differential equation can be expected to describe the acoustic middle ear reflex system adequately.

The phase transfer function shows the time lag of the different Fourier components in relation to the input (dots of Fig. 1, upper right). When the phase lag of the open loop system is 180° (+ n · 360°) there is risk of oscillation in the system. If the amplitude transfer function at this frequency is above 1 (0 dB) the system will oscillate with a continuously increasing amplitude (instability). Thus, it is important to know the characteristics of the system in this frequency region in order to predict its degree of stability.

A certain amplitude characteristic implies a certain minimum phase change, *i.e.* there is a minimal value for phase shift at each frequency. If a system has a lowpass characteristic with a (negative) slope of 12 dB/octave, its minimum phase change is — 180° at high frequencies. In a system with 18 dB/octave, the corresponding minimum phase shift is — 270°. In most biological systems there is a latency time that adds to the minimum phase shift. This additional phase shift is proportional to the frequency. The dots of Fig. 1 (upper right graph) show the total phase shift of the middle ear reflex system. The triangles show the phase shift after subtracting the phase shift due to latency.

The latency can either be determined directly from the time function responses, or from the slope of the phase transfer function at high frequency. Measurements in time-domain are uncertain for several reasons. Due to the gradual onset of the reflex response it is difficult to decide the point of departure from the baseline. Background noise adds variability and lag due to the filters used in the recording apparatus contributes to the latency. In the present study latency was determined from phase curve. The value obtained thereby becomes based on information in the response curve as a whole and corrections for filtering effects are easy.

Figure 1 (lower graphs) shows the amplitude (dots, left graph) and phase (dots, right graph) values of the calculated Fourier transform based on differentiated step responses. The continuous line shows the transfer function of the model describing the properties of the reflex. The model is a second-order differential equation including a transport delay. Its Fourier transform is

$$G\ (j\omega) = \frac{Ke^{-T_1 j\omega}}{(j\omega + a)\,(j\omega + b)}$$

where K includes steady-state gain, T_1 represents the latency (sec), a and b are parameters (1/sec) and $j\omega$ is the complex frequency.

quencies of stimulation It was found that the presence of oscillations in the reflex response amplitude was *strongly* correlated to attenuation of stimulus sound. It was thereby possible to judge from single responses if the stimulus sound was attenuated by the muscle contractions A lack of oscillation did not, however exclude an attenuation of the stimulus. This procedure was utilized for frequencies between 4 0 kHz and 8 0 kHz since in this range responses did not regularly reach sufficient amplitude to influence the stimulus and thus to justify a laborious analysis based on stimulus-response curves This shortcoming was due to limitation in the stimulus earphones.

It is interesting to note that the threshold for attenuation coincided with the reflex threshold only for the lowest frequency investigated 0.5 kHz (Fig 2) At higher frequencies only responses well above threshold for impedance change at 800 Hz influenced sound transmission. The threshold for the influence on transmission was therefore nearly independent of frequency at 90—100 dB SPL. Improvement of sound transmission during middle ear muscle contraction was only occasionally observed and it had so small a value that it could not be differentiated from normal variability in a reliable manner

In order to characterize the magnitude of the influence on sound transmission, the concept efficiency of regulation (or regulatory efficiency) was introduced (II) It was defined as the slope of the curve showing the relation between sound pressure level in dB (re. ipsilateral reflex threshold) and the attenuation of sound expressed in equivalent decrease in sound pressure level (re stimulus sound pressure) Above threshold for attenuation the regulatory efficiency was about 0 7 i e 0 7 dB attenuation per 1 0 dB increase in sound pressure level in the ear canal (0 7 dB/dB) This value was nearly independent of the frequency of the stimulus tone and refers to closed-loop conditions, *i e* when the stimulus is attenuated by the muscles

For a quantitative description, it is often more important to know the equivalent magnitude of attenuation when the stimulus is not itself influenced by the muscle contraction (open-loop). Such is the case when the middle ear muscles are inactivated in the stimulus ear or when a high frequency sound elicits a contraction which does not influence the sound itself (the light shaded of Fig. 2). Such a sound might attenuate a simultaneously present low frequency sound which has intensity below reflex threshold. The steady state open-loop efficiency of regulation was found to be about 2 dB per 1 0 dB increase above reflex threshold (2 dB/dB). This seems to indicate that a 2 0 kHz tone 10 dB above reflex threshold (not itself influenced by the contraction) would attenuate a simultaneously present 0.5 kHz tone below reflex threshold by 20 dB. This very high value could not be verified experimentally the value calculated from the recordings was 5—10 dB This discrepancy was probably due to the above-mentioned fact that the slope of the impedance-change stimulus-response curve was steeper at 0.5 kHz than at 2.0 kHz.

The attenuating efficiency expressed as "dB attenuation per per cent increase in impedance change is probably more generally applicable but is still more complicated to express in simple mathematical terms. A numerical transformation can be made when stimulus-response curves for impedance change are available at the sound frequencies of interest

The steady-state open-loop gain equals (K/ab in equation on page 14) was estimated to 4 corresponding to the open-loop efficiency of regulation 2 dB/dB.

The St was found to be the most important regulator of sound transmission. Above 2 0 kHz, only the St reflex contributed to the attenuation of the sound. At 0 5 kHz the TT provided about 0.2 dB (above its theshold) and the St about 0.5 dB of the *total* regulatory efficiency of 0 7 dB per 1.0 dB increase in sound pressure.

B DYNAMIC PROPERTIES (I II, III)

The temporal characteristics of the reflex activity was investigated in two steps. a) qualita

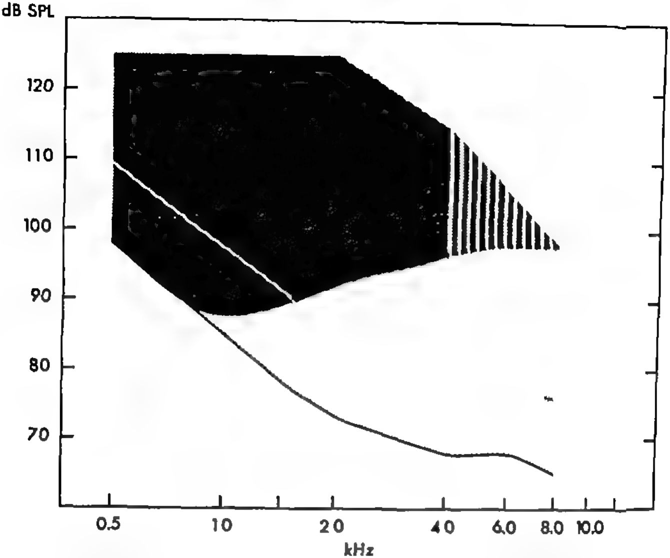

Fig 2 Static properties of acoustic middle ear reflex. Threshold of total reflex (St in conjunction with TT) is shown by the thin continuous line and it is identical to St threshold Threshold of TT is shown by thin white line Dark shaded area shows region where single pure tones are attenuated by the middle ear muscle contraction elicited by the pure tone itself (Copied from II)

individual variability was great. At 2.0 kHz the threshold covered nearly a 40 dB range. The reproducibility for individual rabbits was, however good (Borg, 1972 b)

The dynamic range was arbitrarily defined as the range (in dB) between the sound levels that resulted in a response amplitude between 10 and 80 % of the maximum obtainable impedance change. It was observed to be dependent on sound frequency This range was smaller at low frequencies (15 dB at 0 5 kHz, total reflex) than at high frequencies (28 dB at 4 0 kHz) The isolated ipsilateral St reflex did not differ from the total reflex with respect to dynamic range and shape of the stimulus response curve. On the other hand the TT reflex (when in conjunction with the St reflex) had a less steep stimulus-response curve especially at low frequency and this curve did not regularly reach 80 % (of its maximum when isolated) within the intensity range available

2 Regulation of sound transmission (II)

The thick continuous line in Fig 2 shows the lowest sound level for which attenuation of the stimulus tone was noted The broken line above 4 0 kHz is an extrapolation based on indirect observations of the attenuation Such indirect assessment was based on the presence of oscillations in the reflex response. For lower fre

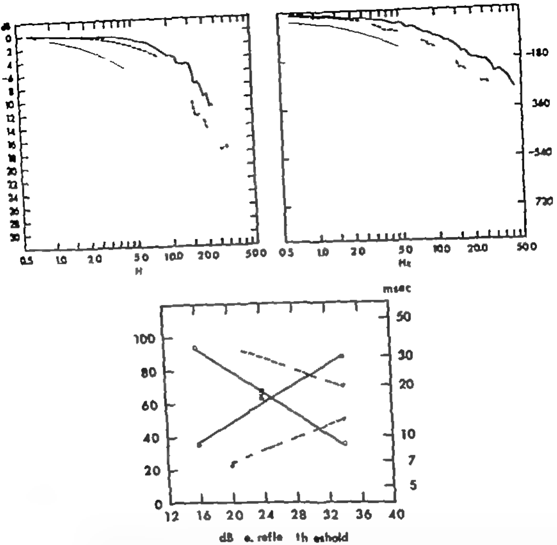

Fig. 3. *Upper graphs.* Frequency transfer function for onset of open-loop step response to contralateral stimulation with 2.0 kHz stimuli (Bode plot). Amplitude of sinusoidal components as function of frequency is shown to the left and phase shift to the right. ——— *112 dB SPL, 99 % of maximal impedance change response amplitude,* - - - 102 dB SPL, 89 % ····· 94 dB SPL, 50 %. *Lower graph.* Parameters of mathematical model for open-loop properties of the total reflex (circles, continuous lines) and the isolated TT reflex of the same animal (triangles, broken lines). Filled symbols show a (=b), left scale. Open symbols show latency T right scale.

tated step responses to onset of a tone burst at three different intensities: 112 dB SPL (giving impedance change of 99 % of maximal response: continuous line), 102 dB SPL (89 % broken line), 94 dB SPL (50 % dotted line).

The amplitude transfer functions were characterized by cut-off frequencies which in this case increased from 2.5 Hz to 9.4 Hz as the stimulus intensity was increased from 16 to 34 dB above reflex threshold. The slope of the high frequency roll-off was about — 12 dB/octave.

The phase transfer functions were characterized by the frequency where the phase shift reached —180°. This frequency varied with stimulus intensity much the same way as the

tively by observation of reflex responses and b) quantitatively by calculating frequency transfer functions and mathematical models. Due to the *nonlinearities observed qualitatively* the quantitative analysis had to be accomplished at several amplitude levels and separately for onset and decay The open loop system was subjected to the most thorough analysis which however could only be performed for the crossed reflex system. The difference between ipsilateral and contralateral reflex properties was determined for the closed loop system and thereafter used to determine the ipsilateral open loop reflex properties. Furthermore, separate analyses of the total reflex, the isolated St reflex and the isolated TT reflex, were made. The emphasis was placed on the total reflex

1 Qualitative studies (I II)

Observations of the reflex responses gave basic information about their time course. The responses obtained with the St intact in the stimulus ear (closed loop) often showed oscillations in the responses in both ears. They were most prominent at 0.5 kHz but were seen up to 8 0 kHz. Their frequency increased, as a function of sound level, an effect which was most prominent at stimulation with low sound frequency Their amplitude increased somewhat when the TT was cut in the stimulus ear The isolated TT rarely showed oscillations.

The open loop responses were obtained in the contralateral ear after inactivation of the muscles in the stimulated ear Denervation of the St in the stimulus ear abolished the oscillations in both ears.

The time course of the responses showed that nonlinear elements existed in the reflex loop Two types of nonlinearities were observed (a) the rise time decreased at increased sound intensity and (b) the onset of the responses was usually faster than the decay

No differences were found in the open-loop properties between the St reflex and the total reflex. The isolated TT differed from the total reflex in being slower and less dependent on level and direction of stimulus change

2 Quantitative studies (III)

Certain basic properties were observed directly in the time course of the responses. The value of essential parameters as well as a mathematical model of the dynamic properties of the middle ear muscle reflex activity were determined from the frequency transfer functions. Due to the nonlinearities, generally valid models of the reflex could not be designed The characteristics of the system in response to stimuli with rapidly varying amplitude were concluded to be modelled more adequately than those in response to slowly varying stimuli. Experimental evidence was available to allow the assumption that the reflex system behaved approximately linearly for the former signals. The onset and the decay of step properties were determined separately in response to the onset or the decay of stimulus tone bursts. Only a small number of animals were analysed quantitatively They were, however selected on the basis of their time functions and regarded to represent typical, or in some cases illustrative, examples of reflex properties.

a *The onset open-loop frequency transfer functions* were calculated from the crossed reflex responses after inactivation of the muscles in the stimulated ear It appeared that it was sufficient to denervate the St alone to obtain the open loop characteristics. Since only the crossed reflex system transfer properties could be obtained directly the ipsilateral open loop characteristics were computed by correcting those of the contralateral reflex for the differences between ipsilateral and contralateral reflex systems. This correction was obtained from the closed loop system (see next section) Since the analysis was made in the frequency-domain, the correction could be accomplished simply by subtraction of amplitudes (in dB) and phase angles

Figure 3 shows the frequency-domain transfer function of the crossed total middle ear reflex open loop system of one animal Amplitude characteristics are shown in the left upper graph and phase angles in the right upper graph The transfer functions were obtained from differen

frequency-specificity of the dynamic properties of the reflex arc.

b. The decay frequency transfer functions were described by the same general type of transfer function as the onset properties. The decay properties were slower than the onset properties and, in contrast to onset, the time constants became longer at increases in the sound level. The latency of the decay however was shorter than that of the onset. This difference might indicate that it took some time to reach threshold for the neurons of the reflex arc and also to take up slip in the mechanical response during the contraction. Thus, the relaxation latency was probably a better expression of the pure transport time than onset latency. It was less dependent on stimulus intensity than the onset latency and its value ranged from 5 to 10 msec.

For the isolated TT reflex, the onset and decay properties differed less from each other than was the case for the total reflex. The onset and the decay responses of the isolated TT reflex could be described by the same models, the only difference being the parameter values.

c. The closed-loop frequency transfer functions were obtained for the ipsilateral and the contralateral total reflex, the TT reflex and the ipsilateral St reflex. The amplitudes of the computed transfer functions of the total reflex and the isolated St reflex in the closed-loop situation showed an intensity dependent resonance peak. At 2.0 kHz this peak could only be seen in responses which were above 80 % of maximal impedance change. At 0.5 kHz clearcut peaks were seen at response amplitudes above about 30—40 % of maximal response. The frequency of the peak increased up to about 20 Hz as the stimulus level was increased. The lower frequency limit was 15 Hz at 2.0 kHz and about 8 Hz with a 0.5 kHz stimulus tone. There was good agreement between the oscillation frequency of the closed loop system and the frequency for which the phase shift of the open system was —180°. On two occasions, the isolated TT reflex transfer function showed a resonance peak. The frequency was about 10 Hz.

The closed-loop characteristics were studied ipsilaterally as well as contralaterally. Quantitative comparisons could thus be made and formed the basis for the above-mentioned calculation of the ipsilateral open-loop characteristics from the crossed reflex data.

C. DIFFERENCES BETWEEN UNCROSSED AND CROSSED REFLEX (I, III)

It was shown that the ipsilateral reflex had a somewhat higher sensitivity to sound than the crossed reflex. This difference was observed both in the total reflex and in the bilaterally isolated TT reflex and it increased towards low frequency and high intensity. The differences in the threshold of the total reflex were small (less than 2 dB), but significant at 0.5 and 2.0 kHz ($p \leq 0.0001$). At 80 % of maximal amplitude, it was about 5 dB (at 0.5 kHz) which corresponded to a difference in response amplitude of nearly 20 %, *i.e.* when the ipsilateral response is 80 %, the crossed response is 60 % of maximal ipsilateral amplitude. The maximal response amplitude obtained in the contralateral ear was only at the most a few per cent below that of the ipsilateral reflex. It could not be excluded that they would reach the same amplitude at higher sound levels than those available.

The dynamic properties of simultaneously recorded ipsilateral and contralateral reflexes were also found to differ. The amplitude transfer function of the crossed total reflex and of the crossed isolated TT reflex were slightly attenuated compared to the corresponding ipsilateral reflex obtained at the same sound intensity.

For the total reflex this difference was more pronounced at high sound intensities, whereas it was nearly independent of intensity for the TT reflex. The phase shift was also greater for the crossed reflex. The differencies both in amplitude and phase response are compatible with an additional neuronal link in the crossed St reflex arc (Borg, 1972 *e*).

cut-off frequency It increased from 7 2 to 20 6 Hz in the intensity range studied Thus, the results showed that the system became faster the higher the stimulus intensity· the cut-off frequency increased and the phase shift decreased at a particular frequency

On the basis of the frequency transfer function a mathematical model was designed to describe the middle ear reflex system It was found that the response of the reflex could be approximated by a second-order system with a transport delay

$$G_o(j\omega) = \frac{Ke^{-T_1 j\omega}}{(j\omega + a)(j\omega + b)}$$

The parameters T_1 a and b were found to be dependent on stimulus intensity K was not determined in these calculations K/ab was in other experiments estimated to about 4 (II)

The lower graph of Fig. 3 shows the values of the parameters of the model as a function of stimulus sound intensity *The filled symbols* show inverted values of time constants (left scale) and the open symbols show the latency (right scale, logarithmic) The abscissa shows sound level in dB re. the threshold of the total reflex The continuous lines show the onset properties of the total reflex the broken lines show onset properties of the isolated TT reflex of the same animal The parameters were approximated by straight lines by the least mean-square criterion

It is seen that parameters a b increased (the time constants, the inverted values of a and b decreased) as sound level increased This means that the responses became faster The latency (T_1) decreased simultaneously

The isolated TT reflex properties could also be described by a second-order differential equation with a transport delay The parameters were smaller (broken lines of Fig. 3 lower graph) *i e* the contraction was slower and the latency was longer than for the total reflex. The parameters were dependent on intensity

$\text{Log } T_1 = -0\,019\,x - 1\,20$

$a\ (=b) = 1\,81\ x + 0\,60$

x is intensity in dB re TT threshold The variation in the values of the parameters as a function of sound level was less for the model of the isolated TT than for that representing the total reflex. In the case shown in Fig. 3 the isolated TT reflex threshold was 7 dB higher than the threshold of the total reflex A compensation for this difference in excitability (shift of the broken lines 7 dB to the left) decreased the difference in parameters between the total reflex and the isolated TT reflex but did not totally abolish it

Figure 3 shows the open loop properties of the crossed reflex. The ipsilateral reflex transfer function was obtained for the total reflex after subtracting the transfer properties of the crossing neural connections. By this procedure the values of the intensity dependent parameters for the model of the ipsilateral total reflex were obtained (another animal)

$$\text{Log } T_1 = 0\,026\ x - 1.20$$
$$a\ (=b) = 6.54\ x - 24\,9$$

x is in dB re. reflex threshold. One example of transfer function of ipsilateral total reflex is shown in Fig. 1 (lower graphs) The dots show experimental values after correction for difference between ipsilateral and contralateral systems, and the continuous lines show the approximated model.

The dynamic properties of the St reflex were assumed to be closely similar to those of the total reflex. Thus, these two situations could be represented by the same model This statement was based on comparisons of the closed loop transfer functions and time-course of open loop responses.

The results of experiments with *stimuli at different* frequencies implied that the onset step response properties were dependent on the frequency of the stimulus tone The open loop properties obtained with 0.5 kHz stimulus were slower and had lower cut-off frequencies. The frequencies where a —180 phase shift was reached were lower than those obtained at 2.0 kHz. The number of available experiments analysed quantitatively was too small to allow definite conclusions to be drawn on this point. These results, however tentatively indicate a

frequency-specificity of the dynamic properties of the reflex arc.

b The decay frequency transfer functions were described by the same general type of transfer function as the onset properties. The decay properties were slower than the onset properties and, in contrast to onset, the time constants became longer at increases in the sound level. The latency of the decay however was shorter than that of the onset. This difference might indicate that it took some time to reach threshold for the neurons of the reflex arc and also to take up slip in the mechanical response during the contraction. Thus, the relaxation latency was probably a better expression of the pure transport time than onset latency It was less dependent on stimulus intensity than the onset latency and its value ranged from 5 to 10 msec.

For the isolated TT reflex, the onset and decay properties differed less from each other than was the case for the total reflex. The onset and the decay responses of the isolated TT reflex could be described by the same models, the only difference being the parameter values

c The closed-loop frequency transfer functions were obtained for the ipsilateral and the contralateral total reflex, the TT reflex and the ipsilateral St reflex The amplitudes of the computed transfer functions of the total reflex and the isolated St reflex in the closed loop situation showed an intensity dependent resonance peak At 0 kHz this peak could only be seen in responses which were above 80 % of maximal impedance change At 0 5 kHz clearcut peaks were seen at response amplitudes above about 30—40 % of maximal response The frequency of the peak increased up to about 20 Hz as the stimulus level was increased The lower frequency limit was 15 Hz at 2 0 kHz and about 8 Hz with a 0 5 kHz stimulus tone. There was good agreement between the oscillation frequency of the closed-loop system and the frequency for which the phase shift of the open system was —180° On two occasions, the isolated TT reflex transfer function showed a resonance peak. The frequency was about 10 Hz.

The closed-loop characteristics were studied ipsilaterally as well as contralaterally Quantitative comparisons could thus be made and formed the basis for the above-mentioned calculation of the ipsilateral open-loop characteristics from the crossed reflex data.

C. DIFFERENCES BETWEEN UNCROSSED AND CROSSED REFLEX (I III)

It was shown that the ipsilateral reflex had a somewhat higher sensitivity to sound than the crossed reflex. This difference was observed both in the total reflex and in the bilaterally isolated TT reflex and it increased towards low frequency and high intensity The differences in the threshold of the total reflex were small (less than 2 dB) but significant at 0 5 and 2 0 kHz ($p < 0.0001$) At 80 % of maximal amplitude, it was about 5 dB (at 0 5 kHz) which corresponded to a difference in response amplitude of nearly 20 %, *i e* when the ipsilateral response is 80 %, the crossed response is 60 % of maximal ipsilateral amplitude The maximal response amplitude obtained in the contralateral ear was only at the most a few per cent below that of the ipsilateral reflex It could not be excluded that they would reach the same amplitude at higher sound levels than those available

The dynamic properties of simultaneously recorded ipsilateral and contralateral reflexes were also found to differ The amplitude transfer function of the crossed total reflex and of the crossed isolated TT reflex were slightly attenuated compared to the corresponding ipsilateral reflex obtained at the same sound intensity

For the total reflex this difference was more pronounced at high sound intensities, whereas it was nearly independent of intensity for the TT reflex The phase shift was also greater for the crossed reflex. The differencies both in amplitude and phase response are compatible with an additional neuronal link in the crossed St reflex arc (Borg, 1972 e)

General discussion

The results of the present study will be discussed in four parts. a) they will be related to other information on the physiology on the middle ear reflexes of animals and man, b) present knowledge will be compiled as a phenomenological description of the rôle of the acoustic middle ear reflexes in the auditory system c) the acoustic middle ear reflexes will be related to the OC efferent system and d) some general ideas on the rôle of feed-back control in *sensory systems will be presented on the basis* of the present results.

A BASIC ACOUSTIC MIDDLE EAR REFLEX PROPERTIES IN ANIMALS AND IN MAN (I II III)

The information presented in the present studies on the properties of the acoustic middle ear reflexes in rabbits was obtained under conditions which justify comparisons to available results in man. The recording and stimulating technique used was identical to that used earlier in several studies in man (Møller 1961 1962 a 1962 b Borg, 1968)

1 Excitability (I)

Excitability of the St reflex (measured as the total reflex) of the rabbit was found to be significantly higher *i.e.* the threshold was lower than that of man by the order of 10—20 dB over a wide frequency range In man, an acoustic TT reflex is not regularly present. According to Lidén et al (1970) it can be recorded in a small fraction of normal subjects (13 %) Other authors deny the presence of a specific acoustic TT reflex in man. They have only found TT responses as part of startle reactions to acoustic and nonacoustic stimuli (Klockhoff 1961 Djupesland 1967) Thus, the interspecies differences are at least equally prominent with regard to the acoustic TT reflex as for the St reflex.

These comparisons are valid for ipsilateral pure tone stimulation. Noise stimuli (Møller 1962 a McRobert et al., 1968 Flottorp et al., 1971) and bilateral stimulation (Møller 1962 a) have been used in man and are likely when used in conjunction to lower the threshold by up to 20 dB There is no experimental data in support of an assumption that the relation of the excitability between rabbit and man would be different for complex stimuli than for pure tones.

Studies in the cat show extremely variable results which probably are due both to the methods used (restrainment of animals, free field stimulation, chronically implanted electrodes) and to a greater variability inherent in the reflexes of cats. It was concluded that the average excitability does not significantly differ between the cat and the rabbit. There is thus a generally higher excitability of the middle ear muscles in animals than in man. Consequently great care should be taken in the application of data obtained from animals with regard to the function of the reflexes in man in order to avoid overestimation of situations wherein the muscles are active.

2 Regulation of sound transmission (II).

The attenuation of sound transmission is similar in the rabbit and man with respect to efficiency of regulation, which is about 0 7 dB/dB under closed loop conditions in both species (man Borg, 1968 rabbit II) This equality refers to low frequency sound

In the rabbit the attenuation of sound transmission was found to extend at least up to 8 0 kHz (II) *Lorente de Nó (1935) observed* reflex responses with oscillations in the rabbit as far as to 16 kHz, which is an indirect proof for attenuation at this frequency (II) The oscillations at this frequency in the example shown were, however minute. Evidence from other

studies both in the anesthetized cat (Gisselsson et al. 1957) and the rabbit (Price, 1966) support the conclusion of attenuation of high frequencies in animals.

In studies on human postmortem temporal bones, Neergaard et al. (1963) found influence of forces applied to the St on sound transmission up to 3.5 kHz. In a later study Cancura (1970) did not in general find an influence on sound at and above 2.0 kHz. This failure is in accordance with results of studies using nonacoustic activation of the muscles in the middle ear in human (Pichler & Bornschein, 1957 Reger 1960) It is, however possible that acoustic activation of St in normal humans gives more effective contractions than can be obtained by nonacoustic stimuli and in postmortem temporal bones In such a case, like in the rabbit, a very high level of St activity might influence also frequencies well above 2.0 kHz.

Eventhough there seem to be differences between man and animals both with regard to threshold for activation of the muscles and frequency range of their influence on sound transmission it should be noted that the threshold for influence on sound transmission is about the same (90—100 dB SPL for pure tones) This high threshold value does, of course, not imply that only high intensity sounds are influenced by the muscles On the contrary weak components are attenuated if they coincide with or appear shortly after a strong sound

3 Dynamic properties (III).

The dynamic properties differ markedly between rabbit and man Since no definite data on the onset open-loop transfer function is available in man (the best approximation available is presented by Møller 1962 a) and cat, the closed loop resonance frequency is appropriate to use for comparison In the rabbit it was about 18—22 Hz and in man about 5 Hz (Møller 1962 a). Oscillations appear more regularly in the St than in the TT (Wersäll, 1958 I) In the cat, they have been observed at a frequency of about 15—20 Hz (Okamoto et al., 1954 Elisson & Gisselsson, 1955) and they seem to be more pronounced in the TT than the St in this animal.

Not only do the onset dynamic properties of the reflex in man and rabbit differ but the stability of responses during prolonged (10 seconds to 1 minute) constant stimulation is also in variance. Above 1.0 kHz the reflex responses in man (Anderson et al., 1969 Tietze, 1969) and in the cat (Simmons, 1963) have been found to fail to keep a constant amplitude in contrast to the conditions in the rabbit (Borg & Møller 1968). Only excessive stimulation (130—140 dB SPL) can produce a similar decay in the reflex responses in the rabbit (Wersäll, 1958)

Dynamic nonlinearities were prominent, specially in the total reflex and the isolated St reflex. They were of two types, dependent on amplitude and direction of change of amplitude. On the basis of earlier experiments (Borg, 1971 b) it was concluded that linear methods could be used to analyse the reflex properties for rapidly rising stimuli Such an approach in analysis of a nonlinear system has not been used earlier to the authors knowledge. It leads to a mathematical model of the reflexes valuable for rapidly rising and falling stimuli throughout the dynamic range of the reflexes. This has not been accomplished earlier for nonlinear reflex systems.

II FUNCTIONAL ROLE OF THE MIDDLE EAR REFLEXES

The basic physiology of the middle ear reflexes has been fairly extensively studied. On the other hand, considerably less attention has been paid to analysing their rôle for perception of sound. Several theories and ideas have been advanced to describe the functional rôle of the middle ear muscles, especially with regard to the acoustic reflexes. Wever & Lawrence (1954), Jepsen (1955 1963), Kobrak (1959), Kirikae (1960), Cancura (1970) and Møller (1972) have presented comprehensive reviews of most of these theories.

The ideas cover a wide range of possibilities from listening muscles (Ostmann, 1899) and

protective devices for the cochlea (Müller 1838) to regulation of labyrinthine fluid pressure (Politzer 1861) and protection of the vestibular system from low frequency acoustic vibrations (Cancura 1970) The function of the middle ear muscles is probably relevant to some of these factors whereas others are merely of historical interest. The relevance of these theories will not be directly discussed here.

On the basis of the present results, the following functions of the acoustic middle ear reflexes have been suggested a) extension of dynamic range of the auditory system for intensity (II) b) decrease of masking of low frequency sound on high frequency sound (II) and c) influence on adaptation (II III) Most of these ideas have been presented in one form or another by earlier workers in this field

1 *Extension of dynamic range*

In this context dynamic range means the range of sound pressure level in the ear canal over which the auditory system operates adequately *e g* discriminates significant sound is not fatigued or damaged

It is shown clearly by the present experiments (II) that high intensity sound over a wide frequency range is attenuated by the middle ear muscle contraction The efficiency of this attenuation is such that a 10 dB increase of sound level above threshold for attenuation results in only a 3 dB increase of actual sound input to the cochlea. It can be immediately realized that this feed back attenuation tends to increase the dynamic range of the afferent auditory system

The rôle of the extention of dynamic range has chiefly been described in terms of protection from fatigue or structural damage to the cochlea (for reviews, see Wever & Lawrence, 1954 Cancura, 1970) The attenuation provided by the middle ear muscles i no doubt of protective value decreasing da. ge and fatigue to the cochlea It has been w ll established in animal experiments (Kato 1°13 Taruya, 1953 Hilding, 1961) as well as in human experiments (Fletcher & Riopelle, 1960 and others) that the ear suffers less damage and fatigue from sound exposure if the muscles are contracting during the sound However this effect has been regarded as unimportant by several authors with reference to the rare occurrence of strong sound in nature, the long latency of the reflex and its fatiguability (see *e g* Cancura, 1970) Especially it has been pointed out that the ear is most sensitive to damage at high frequency (around 4 kHz) in man, thus outside the frequency range usually considered to be influenced by middle ear muscle contractions in man. It has, however been overlooked that there might be a casual relation between the great resistance of the cochlea to fatigue at low frequency and the attenuation provided by the middle ear muscles in this frequency range. In fact, a significant increase in susceptibility to low frequency sound exposure has been observed in subjects with decreased or abolished St contractions in man (Lehnhardt, 1959 1960 Smith et al., 1966 Mills & Lilly 1971 Zakrisson & Borg, in manuscript) It is also interesting to observe that the maximal post-exposure shift of hearing threshold occurred within the range of frequencies most essential for understading of speech when the St was paralyzed, but mainly above these frequencies when its function was normal (Lehnhardt, 1960)

A great sensitivity to low frequency sound exposure in the deeply anesthetized cat (depressed middle ear reflexes) has also been found (Price, 1972) In addition, evidence for the existence of a threshold phenomenon in deterioration of cochlear function was obtained in those experiments. Exposing sound above this level (in the range of 140 dB SPL at 0.5 kHz) gave a very prominant decline in the cochlear microphonic potentials of post-exposure test sound. No information was, however presented on a relationship between middle ear reflex attenuation of sound transmission and the threshold for extensive cochlear fatigue.

It is probable that protection is most adequate in relation to sound produced by the individual itself. This idea has gained considerable support by the work of Henson (1965) in the bat (see further p 25)

Protection is, however only one aspect of the extension of the dynamic range of the auditory system. Others, such as improvement of discrimination should also be regarded.

The implication of the extension of dynamic range for the resolution of complex sound are poorly understood since few studies have analysed the auditory discrimination function at high intensity and still fewer have done this with the aim to study the middle ear reflexes

Nonlinearities and distortion products are probably important in determination of the upper limit of the dynamic range of the auditory system. The middle ear is probably not critical in this respect since it has been found to be linear up to at least 130 dB SPL in deeply anesthetized cats in a wide frequency range (Guinan & Peake, 1967) The cochlea, however has long been known to be nonlinear at much lower intensities (see e g a recent study by Rhode, 1971)

Worthington and Dallos (1971) used cochlear microphonics to study the sources of nonlinearity in the inner ear of the guinea pig. One type of nonlinearity appeared at about 80—90 dB SPL. The close correspondence to the threshold for the middle ear reflex is to be noted In an earlier study it was shown that contractions of TT decreased the amplitude of harmonics in the cochlear microphonics of the guinea pig (Stevens & Newman, 1936)

A more direct hint to the rôle of the middle ear reflexes for discrimination at high intensities is obtained from a recent study in man It was shown that subjects with unilateral St paralysis (in Bell's palsy) suffer a significant decrease in their ability to discriminate nonsense monosyllables above about 100 dB SPL (time constant of 100 msec) in the ear with St paralysis as compared to the other ear with normal St function (Borg & Zakrisson, in manuscript) Below about 100 dB SPL discrimination was equal on both sides The discrimination scores were found to be normalized after the function of the St had been regained These results might indicate that the middle ear reflexes prevent a great increase in the generation of distortion products at high sound levels. A close correspondance was found between the threshold for activation of St in the normal ear in response to the test words and the threshold for loss of discrimination in the ear with St paralysis. This correlation implies an adaptation of the St function to the afferent auditory system to an unexpected degree.

There has been much debate about the significance of the fact that the middle ear reflexes are only activated by fairly high level sound High threshold values have been regarded as an experimental artefact (Simmons, 1964 c) High thresholds, however appear reasonable when the high regulation efficiency is regarded. Since in man (Borg, 1968) and in the rabbit (II) only about 3 dB out of a 10 dB increase in sound level reaches the cochlea the slope of the stimulus-response curve thus decreases considerably Such a decrease in slope would decrease sensitivity for small differences in intensity Evidently from the viewpoint of intensity discrimination the reflex thresholds are expected to be above the range of commonly significant sounds The detailed consequences of having a low reflex threshold are difficult to predict since the time characteristics of the reflexes as well as those of the ear must be considered. It can be studied in experiments on subjects with St paralysis where the middle ear reflexes are substituted by an electronic analogue in which the control of sound transmission has variable threshold. Such work is in progress.

The threshold of the reflex attenuation of sound transmission must be regarded also in relation to the natural acoustic environment of animals and man. As a rule the highest sound levels they obtain are coincident with vocalization. In man high levels are encountered in everyday life e.g with children, in excited discussions and laughter In such conditions the attenuation provided by the middle ear muscles can be of importance both for an improvement of discrimination and prevention from fatigue. It can be suggested as a topic for further research to compare intensity range of significant sounds and the reflex thresholds in vari-

protective; devices for the cochlea (Müller 1838) to regulation of labyrinthine fluid pressure (Politzer 1861) and protection of the vestibular system from low frequency acoustic vibrations (Cancura, 1970) The function of the middle ear muscles is probably relevant to some of these factors whereas others are merely of historical interest. The relevance of these theories will not be directly discussed here.

On the basis of the present results, the following functions of the acoustic middle ear reflexes have been suggested a) extension of dynamic range of the auditory system for intensity (II) b) decrease of masking of low frequency sound on high frequency sound (II) and c) influence on adaptation (II III) Most of these ideas have been presented in one form or another by earlier workers in this field

1 *Extension of dynamic range*

In this context dynamic range means the range of sound pressure level in the ear canal over which the auditory system operates adequately e g discriminates significant sound, is not fatigued or damaged

It is shown clearly by the present experiments (II) that high intensity sound over a wide frequency range is attenuated by the middle ear muscle contraction. The efficiency of this attenuation is such that a 10 dB increase of sound level above threshold for attenuation results in only a 3 dB increase of actual sound input to the cochlea. It can be immediately realized that this feed back attenuation tends to increase the dynamic range of the afferent auditory system.

The rôle of the extention of dynamic range has chiefly been described in terms of protection from fatigue or structural damage to the cochlea (for reviews see Wever & Lawrence, 1954 Cancura, 1970) The attenuation provided by the middle ear muscles is no doubt of protective value decreasing damage and fatigue to the cochlea It has been well established in animal experiments (Kato 1913 Taruya, 1953 Hilding, 1961) as well as in human experiments (Fletcher & Riopelle, 1960 and others) that the ear suffers less damage and fatigue from sound exposure if the muscles are contracting during the sound. However this effect has been regarded as unimportant by several authors with reference to the rare occurrence of strong sound in nature, the long latency of the reflex and its fatiguability (see e g Cancura, 1970) Especially it has been pointed out that the ear is most sensitive to damage at high frequency (around 4 kHz) in man, thus outside the frequency range usually considered to be influenced by middle ear muscle contractions in man. It has, however been overlooked that there might be a casual relation between the great resistance of the cochlea to fatigue at low frequency and the attenuation provided by the middle ear muscles in this frequency range. In fact, a significant increase in susceptibility to low frequency sound exposure has been observed in subjects with decreased or abolished St contractions in man (Lehnhardt, 1959 1960 Smith et al. 1966 Mills & Lilly 1971 Zakrisson & Borg, in manuscript) It is also interesting to observe that the maximal post-exposure shift of hearing threshold occurred within the range of frequencies most essential for understading of speech when the St was paralyzed but mainly above these frequencies when its function was normal (Lehnhardt, 1960)

A great sensitivity to low frequency sound exposure in the deeply anesthetized cat (depressed middle ear reflexes) has also been found (Price, 1972) In addition, evidence for the existence of a threshold phenomenon in deterioration of cochlear function was obtained in those experiments. Exposing sound above this level (in the range of 140 dB SPL at 0.5 kHz) gave a very prominant decline in the cochlear microphonic potentials of post-exposure test sound No information was, however presented on a relationship between middle ear reflex attenuation of sound transmission and the threshold for extensive cochlear fatigue.

It is probable that protection is most adequate in relation to sound produced by the individual itself This idea has gained considerable support by the work of Henson (1965) in the bat (see further p 25)

unilateral St paralysis (associated with Bell's palsy) and normal hearing thresholds show a decrease in discrimination scores on the paralysed side compared to their normal ear The threshold for the difference was at speech level of 90—100 dB SPL and noise level of 80—90 dB SPL (Borg & Zakrisson, in preparation)

The middle ear reflex function can thus be considered as compensation for a "weakness of the cochlear function. the mechanisms for frequency analysis introduce a masking effect that at high intensity becomes very extensive. As a speculation, it can be suggested that feed back regulation provides the most economic compensation method with sufficient efficiency

3. *Adaptation.*

In this context adaptation means a decrease of response of the auditory system following sound stimulation. Due to the latency and the rise time of the middle ear muscle reflex response, the attenuation of sound does not occur immedia tely after the onset of the sound, but only after several tenths (rabbit, III) or hundreds (man, Møller 1962 a) of milliseconds Thus, mainly those components are attenuated which follow a strong, reflex-eliciting sound This effect thus contributes adaptation to the auditory periphery (see also Holstein et al 1969) The contrast in the temporal pattern of sound is increased if a strong sound precedes a weaker one Rapid changes in intensity of a sound are enhanced at the expense of sound with constant or slowly varying intensity

It is sometimes reported by patients with unilateral total St paralysis that they perceive an accentuation of echoes (Borg, unpublished) A suppression of an echo can be regarded as an example of adaptation The perception is localized to the head of the patient and is elicited by external sound as well as by the patient's own voice The echoes of external sound disappear if the external meatus is occluded, but the voice echoes remain and are increased However no measurements are available to illustrate this point objectively and quantitatively

According to Wigand and Borucki (1965), separation of double clicks is deteriorated in subjects who have been stapedectomized or who have a Bell's palsy This effect was ascribed to an increase in duration of the response to the clicks when the middle ear muscles were paralyzed. The evidence presented in animal experiments (Wigand, 1965 Wigand & Borucki, 1965) for such an increase in duration does not appear convincing since the recordings shown unfortunately have insufficient signal-to-noise ratio to allow for these conclusions and to differentiate an increased damping from merely the well-known reduction in amplitude (II) Furthermore, such a function of the middle ear muscles in man presupposes a *considerable* degree of spontaneous tonic middle ear muscle contraction in man. Electromyographic recordings show however very slight or no activity in the absence of sound at rest (Fisch & Schulthess, 1963 Salomon & Starr 1963)

4 *The relation between m stapedius and m tensor tympani reflexes*

The present results are in agreement with most earlier studies in showing that the St is more excitable by sound than the TT (I) It has also a dominating rôle in the regulation of sound transmission through the middle ear (II). It can be observed that the St in man (Borg, 1968) has equally great influence on transmission of low frequency sound (0 7 dB/dB at 0 5 kHz) as has the St and TT together in rabbit (approximately 0 5 and 0 2 dB/dB, respectively at 0.5 kHz). It might thus be fruitful to consider the lack of acoustic TT reflex activity in man in this relation the St alone provides sufficient regulation which can be interpreted so there is no need for an acoustic TT reflex.

Some occasional observations of the present study (I) in conjunction with recent tympanometric studies by Ingelstedt & Jonson (1967) might suggest a mainly ventilatory function of the TT

ous species of animals. It is the authors impression that small mammals (cats and rabbits) in general are surrounded by weaker sounds than man. If this assumption and the preceding argumentation are valid it is compatible with the lower reflex threshold observed in cats and rabbits than in man (I)

Thus the acoustic middle ear reflexes can play a rôle to relieve the consequences of imperfections in the afferent auditory system, the middle ear and chiefly the cochlea at the upper end of the dynamic range. These imperfections can be assumed to be more severe, without deteriorating the performance of the system as a whole, in a receptor with feed back regulation than in a corresponding receptor without such a compensatory mechanism The discrimination ability is directly increased by the reflexes for high level sound and performance below reflex threshold might be indirectly improved (see also p 29)

2. *Decrease of masking*

It has long been known from psychoacoustic studies that low frequency sound masks high frequencies to a much higher degree than the reverse (for review of the earlier literature, see Stevens & Davis, 1938 and for a modern review see Scharf 1971) It is generally regarded to be due to the vibration pattern of the basilar membrane. The masking increases rapidly above 40 to 60 dB sensation level (Ehmer 1959) A reduction in the low frequency components of complex sound would therefore increase the detectability for the various spectral components of the sound over a wide frequency range. The validity of this assumption is supported by the abnormally good hearing in noise observed in patients with low frequency hearing loss due to middle ear pathology (paracusis Willisii de Maré & Rösler 1950)

In this relation the fact makes sense that high frequency sound is most effective in eliciting the muscle contraction (rabbit I) although the contraction most readily attenuates low frequency sound (II) In man (Møller 1962 b) the difference between the thresholds for low and high frequency is similar to that in the rabbit (I) Furthermore, also in man low frequency sound is attenuated by all degree of muscle activity (Borg, 1968) whereas high frequencies are, if at all, only attenuated at intensities far above reflex threshold (Borg, 1968) This interaction between low and high frequency can be described as equivalent to lateral inhibition (II) Of course, the feed back attenuation — low frequency sound is attenuated by reflex activity elicited by the low frequency sound itself — is also important in this respect. Stevens & Davis (1938) suggested a reduction of masking to be a possible advantage for hearing provided by the middle ear muscles.

The magnitude of the antimasking effect of the reflexes can be estimated on the basis of the results gained in the present study (and the results by Borg, 1968) and from masking experiments, *e.g* those by Ehmer (1959) and others. A 20 dB reduction in intensity of the masking sound (from 80 to 60 dB sensation level) gives a reduction in masking that is equivalent to a 70 % reduction of the area of masking in the logarithmic frequency intensity plane.

The activation of the middle ear muscles by lightly touching the skin around the ear (Kato 1913 Lüscher 1929 Klockhoff 1961 Djupesland 1967) might also be relevant in this connection. Objects or air streams touching the head are likely to produce some masking noise which thus is attenuated by the middle ear muscle contractions.

The rôle of St reflex for discrimination of speech in low frequency noise was investigated by Lidén et al. (1964) in two groups of patients that had been stapedectomized with two different methods. In one of the methods the St tendon was preserved in the other it was cut. They found that discrimination scores in noise in the patient with St tendons preserved was more seldom deteriorated by the operation than in those with the tendon cut. The authors concluded that their results showed an antimasking effect of the St in man. Preliminary results from discrimination measurements of nonsens words in 700 Hz lowpass filtered noise in subjects with

and keeps the receptor region in suitable length to retain its sensitivity even during shortening of extrafusal muscle fibers (for a recent review see Granit, 1970). One aspect of the rôle of these mentioned *efferent* control systems is thus that they improve the resolution without loss of dynamic range and to a low cost for the organism.

The two efferent systems influencing the response of the cochlea, the middle ear muscles and the OC efferents, can be viewed in relation to range and resolution of the intensity of sound. The OC efferents increase the slope of the stimulus-response curve of the cochlea by depressing response chiefly to low-intensity sound (see e.g. Wiederhold, 1970, Borg, 1971 a). Sensitivity to changes in intensity can thereby be assumed to be enhanced at expence of a temporary increase in threshold.

The middle ear reflexes decrease the slope of the stimulus-response curve above a threshold value of 90—100 dB SPL (II. Borg, 1968). This "compression" allows the cochlea to operate with a steeper stimulus-response curve in the intensity range *below* the reflex threshold than if the slope was constant in the whole dynamic range of the cochlea. The resolution of sound intensity will thereby indirectly be improved in the range below the reflex threshold, the range of most significant sounds. It will also be kept at an acceptable level in the high intensity range where the cochlea operates poorly when deprived of middle ear muscle feed-back regulation (see page 25). Thus, the control systems in the auditory periphery can be conceived also as improving the resolution without decrease of dynamic range.

The results obtained in the present study emphasize as an important function of sensory system control mechanisms the improvement *of resolution at a low cost for the organism* and without decrease of dynamic range.

Summary

1. *The acoustic middle ear reflexes* were analysed in nonanesthetized unrestrained rabbits with respect to their excitability, influence on sound transmission and dynamic properties. Ipsilateral and contralateral contractions of the two middle ear muscles, m. stapedius and m. tensor tympani in separation and in conjunction (the total reflex), were recorded *simultaneously* by measuring changes in the acoustic impedance of the ear. Bursts of pure tone in the frequency range 0.5 to 12.0 kHz at intensities up to *125* dB SPL were used as stimuli.

2. The mean value of the threshold (defined as *10%* of maximal response) of the total reflex was found to be 98 dB SPL at 0.5 kHz and decreased with increasing *frequency at a* rate of about 1 dB/octave *to 2.0 kHz*. Above 4.0 kHz it was nearly constant at about 70 dB SPL.

3. The excitability of the isolated m. stapedius reflex *did not differ* from that of the total reflex whereas the *m. tensor tympani* had a 10 dB higher *threshold* in the whole frequency range.

4. Contractions *of the* middle ear muscles *attenuated the sound transmission* through the middle ear above 90—100 dB SPL, irrespective of sound frequency up to at least 8.0 kHz. The middle ear muscle reflex, working as a closed-loop control system, provided about a 0.7 dB attenuation per 1.0 dB increase in sound level above the threshold for the attenuation throughout a wide frequency range. The equivalent efficiency of regulation of the open-loop system was about 2 dB/dB.

5. The dynamic properties of the reflexes were nonlinear but they could be modelled by second-order differential equations having

C. THE ACOUSTIC MIDDLE EAR REFLEX IN RELATION TO OTHER AUDITORY SYSTEM CONTROL MECHANISMS

The efferent regulators of the auditory system analysed experimentally to some extent — the OC efferents and the middle ear muscles — have both common and different properties. Both are activated as reflexes by auditory stimuli and both are influenced by the CNS (Fex, 1962, 1965 Rupert et al 1968 Borg, 1971 a) Both probably decrease noise masking (regarding the OC efferents, see Dewson 1968 Trahiotis & Elliott, 1970 Nieder & Nieder 1970 Borg, 1971 a see, however Igarashi et al 1972) The two regulators have been found to differ *e g* regarding their effect on latency of auditory nerve response to clicks (N_1) (Desmedt et al., 1971) The OC efferents attenuate N_1 without prolonging the latency in contrast to St contractions. The frequency intensity region where their maximal effects occur also differs. The OC efferents have their main effect on weak sounds in high frequency range (above 2.0 to 3 0 kHz, Wiederhold 1970) whereas the middle ear muscles affect sound of all intensities chiefly of low frequencies (*below about 1 0 kHz, II*) Higher frequencies are attenuated only at maximal middle ear muscle contraction

On anatomical grounds the OC efferents can be proposed to exert their influence with greater frequency specificity than the high pass filtering provided by the middle ear muscles, since each efferent nerve fiber extends only over a small portion of the basilar membrane (Spoendlin, 1970) Furthermore, there is evidence that the organization of the neuronal pathways is fundamentally different for the activation of OC fibers and middle ear muscles by sound (Warr 1969 Osen & Roth 1969 Borg, 1972 d 1972 e)

As yet general statements are premature on the functional relationship between the middle ear reflexes and the OC efferents. The prominent anatomic and physiologic differences imply however that they represent partly different aspects of control of afferent auditory activity

D GENERAL ASPECTS ON CONTROL IN SENSORY SYSTEMS

Two important properties of sensory systems (a) high sensitivity to small changes in stimulus (resolution) and (b) responsiveness over a wide range of parameters of the physical stimulus (dynamic range) imply contradictory functional demands on the sensory systems. A high resolution necessitates *e g* a steep stimulus response relation A large dynamic range implies low threshold and no saturation within the physiological range, which thus tends to decrease the slope of this function. This problem has been solved in various ways for different sense organs.

The human visual system has a high spatial resolution in the fovea centralis. The resolution in the peripheral visual field is considerably lower but sufficient to detect objects suitable for further analysis. By means of efferent mechanisms, the extra-ocular muscles, the region of high resolution is moved to analyse the object.

Theoretically similar effects could be achieved in other ways. For instance, the retina could have the same extremely high density of cones peripherally as centrally and a corresponding amount of optic nerve fibers. Unaltered refinement of central analysis performed simultaneously throughout the visual field offers an equally good or a better solution to the compromise between range and resolution than does the eye position control system However it subjects the central nervous system to a good deal of extra work.

The gamma-efferents of the muscle spindles constitute another system which from a restricted *point of view* can be regarded to have a function to improve the compromise between the demands on range and resolution. Impulse flow in the gamma-efferent shortens the contractile portion of the intrafusal muscle fiber

and keeps the receptor region in suitable length to retain its sensitivity even during shortening of extrafusal muscle fibers (for a recent review see Granit, 1970). One aspect of the rôle of these mentioned efferent control systems is thus that they improve the resolution without loss of dynamic range and to a low cost for the organism.

The two efferent systems influencing the response of the cochlea, the middle ear muscles and the OC efferents, can be viewed in relation to range and resolution of the intensity of sound. The OC efferents increase the slope of the stimulus-response curve of the cochlea by depressing response chiefly to low-intensity sound (see e.g. Wiederhold, 1970. Borg, 1971 a). Sensitivity to changes in intensity can thereby be assumed to be enhanced at expence of a temporary increase in threshold.

The middle ear reflexes decrease the slope of the stimulus-response curve above a threshold value of 90—100 dB SPL (II. Borg, 1968). This "compression" allows the cochlea to operate with a steeper stimulus-response curve in the intensity range *below* the reflex threshold than if the slope was constant in the whole dynamic range of the cochlea. The resolution of sound intensity will thereby indirectly be improved in the range below the reflex threshold, the range of most significant sounds. It will also be kept at an acceptable level in the high intensity range where the cochlea operates poorly when deprived of middle ear muscle feed-back regulation (see page 25). Thus, the control systems in the auditory periphery can be conceived also as improving the resolution without decrease of dynamic range.

The results obtained in the present study emphasize as an important function of sensory system control mechanisms the improvement of resolution at a low cost for the organism and without decrease of dynamic range.

Summary

1. The acoustic middle ear reflexes were analysed in nonanesthetized, unrestrained rabbits with respect to their excitability, influence on sound transmission and dynamic properties. Ipsilateral and contralateral contractions of the two middle ear muscles, m. stapedius and m. tensor tympani in separation and in conjunction (the total reflex), were recorded simultaneously by measuring changes in the acoustic impedance of the ear. Bursts of pure tone in the frequency range 0.5 to 12.0 kHz at intensities up to 125 dB SPL were used as stimuli.

2. The mean value of the threshold (defined as 10 % of maximal response) of the total reflex was found to be 98 dB SPL at 0.5 kHz and decreased with increasing frequency at a rate of about 1 db/octave to 4.0 kHz. Above 4.0 kHz it was nearly constant at about 70 dB SPL.

3. The excitability of the isolated m. stapedius reflex did not differ from that of the total reflex whereas the m. tensor tympani had a 10 dB higher threshold in the whole frequency range.

4. Contractions of the middle ear muscles attenuated the sound transmission through the middle ear above 90—100 dB SPL irrespective of sound frequency up to at least 8.0 kHz. The middle ear muscle reflex, working as a closed-loop control system, provided about a 0.7 dB attenuation per 1.0 dB increase in sound level above the threshold for the attenuation throughout a wide frequency range. The equivalent efficiency of regulation of the open-loop system was about 2 dB/dB.

5. The dynamic properties of the reflexes were nonlinear but they could be modelled by second-order differential equations having

parameters dependent on both amplitude and direction of change of amplitude. The total reflex and the isolated m stapedius reflex had almost identical dynamic properties, whereas the isolated m. tensor tympani reflex was slower

The reflex properties were discussed in relation to hearing in man and other animals. The results obtained in the present study suggest three main functions of the acoustic middle ear reflexes a) extension of the dynamic range of the auditory system with respect to intensity b) decrease of masking of low frequency sound on high frequencies and c) contribution to adaptation whereby changes in intensity are enhanced In a broader sense, the results serve to illustrate that sensory system control mechanisms provide solutions of demands for high resolution and wide range at low cost to the organism

Acknowledgements

I am deeply indebted to my teacher Assist. Professor Aage R. Møller Division of Physiological Acoustics Department of Physiology Karolinska Institutet under whose guidance I have had the privilege to work. He introduced me to the field of auditory physiology and he has inspired advised and assisted me throughout the performance of this work. My sincere gratitude is extended to Professor Carl-Gustaf Bernhard Department of Physiology for encouragement, advice and support of my work I wish to thank my colleagues on the staff at the Department of Physiology for numerous discussions and valuable criticism. Dipl Ing Gunter Rosler and Professor Courtney Stromsta have been of invaluable help in discussions during the preparation of the manuscripts. I wish to thank Mrs. Monica Eriksson, Miss Yvonne Lundgren Miss Carina Erickson, Mrs. Agnes Kihlberg Szabo and Mrs Danuta Sztarkier for their skilful technical assistance. Mr Arne Österman and his staff are gratefully acknowledged for breeding rabbits of the small chinchilla strain which were used in my experiments.

For their skill and patience with my manuscripts I am grateful to Mrs Karin Stenbäck Mrs. Birgitta Flood and Mrs. Kate Rundqvist

The investigations were supported by grants from Karolinska Institutets fonder Karolinska Institutet and from Sällskapet for Medicinsk Forskning

PREFACE

This supplement reports the proceedings of the Symposium on Ménière's Syndrome sponsored by N.V. Philips-Duphar and held in the Hotel Bouwes at Zandvoort in The Netherlands on Thursday 3rd September 1970. The names and addresses of the participants in the symposium are listed on preceding pages.

A connection between the sponsors of the Symposium and the drug betahistine hydrochloride is obvious insofar as much of the symposium was devoted to the pharmacology and activity of this drug. However, it was felt by myself and others that the material of the Symposium was of such value, in purely scientific and medical terms, that it merited publication. Accordingly, as Chairman of the Symposium, it has been my pleasure to prepare the proceedings in the form of an Acta Oto-laryngologica Supplement. As such, the proceedings are complete except for the full text of Professor Jongkees' paper and for the discussions following each paper. On the other hand I have added, retrospectively, a summary of the panel discussion with the intention of increasing its general value.

An accidental loss of the first and already carefully-edited transcript caused a considerable delay in publishing these proceedings. Nevertheless the material is considered to be of more than sufficient merit and value to warrant its publication now in spite of the delay.

As editor, I would like to record my thanks to the many persons who attended the Symposium and have subsequently helped this publication by careful preparation of the texts of their papers and/or by vetting of their contributions to the panel discussions which, inevitably, I had to edit heavily in order to convert it from colloquial to written expression.

MÉNIÈRE'S — A SYNDROME OR DISEASE?

L. B W Jongkees

From the Wilhelmina Gasthuis, University of Amsterdam, The Netherlands

ABSTRACT

The name of Dr Prosper Ménière is connected with a syndrome consisting of cochlear vestibular and (para)-sympathetic symptoms. This syndrome indicates peripheral pathology It is unnecessary unwise, and misleading to use the name Ménière (with or without prefixes like para- or pseudo-) for vestibular pathology because in these cases the name Ménière indicates nothing but lack of knowledge.

Dr Ménière was also the first who described many causes of the syndrome that bears his name, especially those attacks of vertigo that seize the healthy patient, take away his forces, make him vomit, and strike him down until, after the period of sleep, he rises again, but for a slight deafness. It is a good habit to call this Ménière s disease.

Today we know that a hydrops labyrinthi is the anatomo-pathological substrate for Morbus Ménière, but we do not know what this hydrops really stands for neither do we know its genesis. For this reason the treatment of Ménière s disease is not yet based on solid ground.

ment of Ménière's disorder. These drugs include nicotinic acid, β-pyridyl carbinol, buphenine hydrochloride and cyclandelate, but none has been subject to a controlled clinical trial. However, this criticism cannot be levelled against the use of β-histine, the oral histamine analogue, which is β-(2-pyridyl) ethylmethylamine. Although criticised by Clemis (1969), this drug has been shown in at least two double-blind therapeutic trials (Elia, 1966; Hicks, Hicks & Cooley 1967) to be effective in the control of vertigo in Ménière's disorder. Moreover, apart from hydrochlorothiazide, it is the only method of treatment of Ménière's disorder which has been shown, in a double-blind study, to be more effective than a placebo in the control of the vertigo. The use of this histamine analogue seems rational when one considers Schayer's (1964) hypothesis that histamine is the intrinsic microcirculatory dilator. An alternative means of producing vasodilatation is by paralysis of the cervical sympathetic nerve (Passe & Seymour 1948). This paralysis may be produced temporarily by stellate ganglion block, which may also be used for treating acute attacks of the disorder (Wilmot, 1957), or permanently by cervicodorsal sympathectomy (Lewis, 1951; Wilmot, 1961; 1969). At the turn of the century, G. Ferreri (1903) (quoted by Brunetti, 1934) resected both superior cervical sympathetic ganglia in a man with intractable tinnitus and the results were satisfactory and lasting. By means of the same operation, a quarter of a century ago, Mogan & Baumgartner (1945) abolished the vertigo and ameliorated the tinnitus in a patient who was subsequently shown to have Cogan's syndrome, so that it would appear that the indications for the operation, if accepted, are not confined to Ménière's disorder. However, Johnson (1954) considered that the results of the operation in Ménière's disorder were disappointing, and Strong (1957) reported that the success rate was less than 30 per cent. It may thus not be surprising that the operation was recently referred to as "an abandoned surgical technique for Ménière's disease" (Clemis, 1969). However, unlike the various operations upon the vestibular labyrinth which are designed to conserve hearing, but which sometimes damage it, this operation does not in itself at any time produce damage to residual hearing. Moreover, although hearing may not be improved, there is a one-third chance of a reduction in distortion and an intractable tinnitus may be relieved immediately. Sympathectomy we therefore find has a place in the management of bilateral disease, and where the hearing level is deteriorating despite medical measures, especially where dysacusis and troublesome tinnitus are conspicuous symptoms, but where patients are under the age of 55. Unfortunately, as Harrison & Naftalin (1968) point out, the results of stellate ganglion block seldom give any real helpful lead in the selection of cases for sympathectomy, and complications from injections into the region of the ganglion, by whichever route, are by no means rare and may be serious.

Proceedings of the Symposium on Ménière's Syndrome Zandvoort September 3 1970

REVIEW OF TREATMENT OF MÉNIÈRE'S SYNDROME

R. Hinchcliffe

From the Institute of Laryngology and Otology University of London England

The treatment of a patient suffering from Ménière's syndrome is of course dependent upon which particular disease entity the patient is afflicted with. Ménière's syndrome is defined as a syndrome of paroxysmal attacks of vertigo in association with tinnitus and a gradually developing sensorineural hearing loss. A syndrome being a symptom-complex may cover a number of "disease entities" As well as including Ménière's disorder Ménière's syndrome may be due to a blood pigment autoimmune disorder (Vogt Koyanagi-Harada syndrome) polyarteritis nodosa (Cogan's syndrome) syphilis (late congenital) or trauma (perilymph leak) including that arising from operative intervention It may also occur secondary to pre-existing internal ear disease Excluding a perilymph leak which should be treated by tympanotomy and repair of the fistula of the fenestra ovalis, the various disease entities" should, for the most part be treated medically For a syphilitic Ménière's syndrome, ampicillin with or without corticosteroids, is indicated and the latter may also be the drug of choice for some of the other disease entities"

Ménière's disorder might well be termed the idiopathic Ménière's syndrome Mild cases or formes frustes" exist, where the triad of symptoms is incomplete Thus just as all cases of Ménière's syndrome are not cases of Ménière's disorder so all cases of Ménière's disorder may not be cases of Ménière's syndrome. Because of the incompleteness of the symptom complex in these formes frustes of Ménière's disorder they have sometimes been termed atypical or pseudo-Ménière's syndrome As Cawthorne & Hewlett (1954) and Jongkees (1964) have pointed out, many cases of Ménière's disorder respond to explanation and reassurance with or without psychotropic drugs. A five year longitudinal study of patients who were suffering from Ménière's disorder and who were treated conservatively showed no deterioration in their median hearing thresholds which could be attributed to the disorder (Hinchcliffe, 1970) Apart from therapeutic listening" the majority of the patients were receiving psychotropic drugs and were eventually able to discontinue their medication at some period or other during the period under review The most common drug was amylobarbitone and the next most common nortriptyline It is of interest that in a double blind clinical trial using doses of amylobarbitone higher than those used for the patients in the series, Reynolds Joyce, Swift Tovley and Weatherall (1965) showed that the drug was not significantly better than a placebo in the treatment of anxious outpatients. This placebo response should be borne in mind when considering the results reported for the treatment of Ménière's disorder with other methods which are classified in Table I

As Harrison & Naftalin (1968) point out the production of vasodilatation is a natural corollary to the belief that labyrinthine ischaemia is of importance in Ménière's disorder Thus a variety of vasodilator drugs have been used at one time or another in the treat

ment of Ménière's disorder. These drugs include nicotonic acid, β-pyridyl carbinol, buphenine hydrochloride and cyclandelate, but none has been subject to a controlled clinical trial. However, this criticism cannot be levelled against the use of β-histine, the oral histamine analogue, which is β-(2-pyridyl) ethylmethylamine. Although criticised by Clemis (1969), this drug has been shown in at least two double-blind therapeutic trials (Elia, 1966; Hicks, Hicks & Cooley, 1967) to be effective in the control of vertigo in Ménière's disorder. Moreover, apart from hydrochlorothiazide, it is the only method of treatment of Ménière's disorder which has been shown, in a double-blind study, to be more effective than a placebo in the control of the vertigo. The use of this histamine analogue seems rational when one considers Schayer's (1964) hypothesis that histamine is the intrinsic microcirculatory dilator. An alternative means of producing vasodilatation is by paralysis of the cervical sympathetic nerve (Passe & Seymour, 1948). This paralysis may be produced temporarily by stellate ganglion block, which may also be used for treating acute attacks of the disorder (Wilmot, 1957), or permanently by cervicodorsal sympathectomy (Lewis, 1951; Wilmot, 1961, 1969). At the turn of the century, G. Ferreri (1903) (quoted by Brunetti, 1934) resected both superior cervical sympathetic ganglia in a man with intractable tinnitus and the results were satisfactory and lasting. By means of the same operation, a quarter of a century ago, Mogan & Baumgartner (1945) abolished the vertigo and ameliorated the tinnitus in a patient who was subsequently shown to have Cogan's syndrome, so that it would appear that the indications for the operation, if accepted, are not confined to Ménière's disorder. However, Johnson (1954) considered that the results of the operation in Ménière's disorder were disappointing, and Strong (1957) reported that the success rate was less than 30 per cent. It may thus not be surprising that the operation was recently referred to as "an abandoned surgical technique for Ménière's disease" (Clemis, 1969). However, unlike the various operations upon the vestibular labyrinth which are designed to conserve hearing, but which sometimes damage it, this operation does not in itself at any time produce damage to residual hearing. Moreover, although hearing may not be improved, there is a one-third chance of a reduction in distortion and an intractable tinnitus may be relieved immediately. Sympathectomy we therefore find has a place in the management of bilateral disease, and where the hearing level is deteriorating despite medical measures, especially where dysacusis and troublesome tinnitus are conspicuous symptoms, but where patients are under the age of 55. Unfortunately, as Harrison & Naftalin (1968) point out, the results of stellate ganglion block seldom give any real helpful lead in the selection of cases for sympathectomy, and complications from injections into the region of the ganglion, by whichever route, are by no means rare and may be serious.

Goldman (1962) reported that 17 ketosteroid production is low in people with Ménière s disorder and that 90% of such patients show good response to injections of whole adrenal cortical extract, but not to corticotrophin which Maggio Perella & De Vita (1957) had previously found to be effective If Ménière s disorder is a psychosomatic disorder as Fowler & Zeckel (1952) and others contend or a manifestation of the adaptation syndrome then there should be a response to corticotrophin (Groen 1955) Of the two principal types of cortical steroids, i e. the glucocorticoids and the mineralocorticoids, there have been reports not only of the effectiveness of the glucocorticoids (Hauser 1959 Hirata 1963) but also claims for the administration of the mineralocorticoids (Naftalin & Harrison 1961). However according to Schayer s (1964) hypothesis, glucocorticoids, which previously had been shown to have a vasoconstrictor action by Ashton and Cook (1952) moderate the dilator action of histamine. Thus, in the sense that histamine and the glucocorticoids are essentially antagonistic in their action on the microcirculation, one would expect only one (if any) to be therapeutically effective in a microcirculatory disorder and the other compound to actually exacerbate symptoms. The influence of ACTH on patients with Ménière s disorder is, however complicated by the recent demonstration by Gejrot, Fluur & Levi (1966) that patients with Ménière s disorder along with other individuals who have sustained labyrinthine damage, react differently to psychological stress.

We have previously mentioned the effect of psychotropic drugs in ameliorating the symptoms in Ménière s disorder Of the more specific vestibular suppressives, those of the phenothiazine group e g cinnarizine and prochlorperazine appear to be the most effective In this section on "depression of vestibular response" we can for purposes of classification include both administration of streptomycin and vestibular neurotomy since both these procedures interrupt the flow of afferent impulses which signal to the brain the episodic disturbances of labyrinthine function The use of streptomycin depends on the specific vestibulo-toxic action of this antibiotic (Fowler 1948 Hamberger Hyden & Koch, 1949 Graybiel, Schuknecht, Fregly Miller & McLeod, 1967 Schuknecht, 1957) The drug is given in a dose of 1 g three times a day and its effect is monitored by daily caloric tests. The response of the affected ear or the more seriously affected ear if the condition is bilateral, disappears first, when treatment should be stopped Unfortunately compensation of equilibrium is less perfect with older patients. In any case compensation is never complete and all patients persist in having difficulty in walking in the dark (Graybiel et al. 1967) The use of the drug should therefore be confined to patients under the age of fifty years, where both ears are involved and where there has been no response to other medical treatment and where the patient refuses to undergo operation

Vestibular neurotomy has now been used for over forty years and, of the 278 cases operated on by Dandy Green (1959) reported that the vertigo was relieved or improved in 95% of cases but in nearly two-thirds of the cases, the hearing got worse and in 14% of cases the patient eventually became deaf" Tinnitus was reported relieved in 50% of cases. However other series of cases have shown less success (Putnam 1938 Walsh & Adson, 1940) A Canadian series showed that, although the immediate results were good the final results were usually disappointing (Ireland 1949) In many cases the hearing has continued to fall away Moreover it should be remembered that this entails an intracranial operation which is not without risk. The risk, however may be slight Only two of Dandy s patients died, and here the death was due to meningitis which would now be expected to respond to current methods of treatment

Even before Hallpike & Cairns (1938) had demonstrated endolymphatic hydrops as the histological correlate of Ménière s disorder

Mygind (1926) had suggested that alterations in body fluids may play a part in the pathogenesis of Ménière's disorder. There are individual patients whose episodes of vertigo respond to salt and fluid restriction and, using a double-blind technique, Klockhoff & Lindblom (1966) showed that hydrochlorothiazide is beneficial with respect to the hearing loss, vertigo and general condition in Ménière's disorder. The modus operandi for water and salt depletion procedures is uncertain since Perlman, Golding & Cales (1953) failed to demonstrate any consistent effect by either water depletion and loading or salt depletion and loading in cases of Ménière's disorder. Harrison & Naftalin (1968) have shown that the acute attacks of vertigo occur during a phase of sodium diuresis concomitant with a water gain.

A century ago, Knapp (1871) suggested that Ménière's disorder might be analogous to glaucoma and the symptoms be due to increased intralabyrinthine fluid pressure. Portmann, Sr. (1927) followed up this suggestion 55 years later by treating Ménière's disorder by making an opening into the endolymphatic sac. He subsequently performed 60 operations of this type over the subsequent 38 years. In this series, the vertigo was relieved in 93% of cases and the tinnitus and the hearing improved each in about one-third of cases. Thus, so far as the vertigo and the hearing are concerned, Portmann obtained better results than House (1965) obtained for his 243 cases treated with the subarachnoid endolymphatic shunt operation, where the vertigo was said to be improved in three-quarters of the cases and the hearing in 10% only. It is therefore not surprising that Portmann, Jr. (1969) should say: "It seems useless to place a tube in the arachnoidal spaces as proposed by House—a *simple* opening is sufficient to provoke improvement." Moreover, Shambaugh (1966) found that he could obtain the same results with simple exposure of the sac. With such a dummy operation, what could have been better as a control trial to assess the results of the subarachnoid endolymphatic shunt operation? Furthermore, 3 years later Shambaugh (1969) wrote: "My initial enthusiasm for operating upon the endolymphatic sac to improve hearing in Ménière's disorder has steadily cooled. Only once did I duplicate the dramatic success of the first case with return of normal hearing and in only two more cases was there a significant, but not great, improvement of hearing. In all the rest, i.e. 92 per cent of cases, the hearing was unchanged or worse. Insertion of the "teflon" film did not give any better results in my hands than simple decompression." The operation may be complicated by otitic hydrocephalus or meningitis, so that it is not free from hazard. A simpler method of depressing the membranous labyrinth has been devised by Fick (1964), who perforates the centre of the stapes base with a needle. This opening is then enlarged to 1 mm with a burr, more fluid drawn out of the labyrinth, and the mucosa replaced. Although the earlier results for this operation were reported to be very good (relief of vertigo in 90% of cases and improvement in hearing in 65% of cases) the late results have been less good. As Portmann (1969) pointed out, the results obtained by other surgeons who experimented with the procedure are bad and deafness is frequent following the operation. Cody, Simonton & Hallberg (1967) have endeavoured, ingeniously, to improve on this operation by inserting a small prosthesis, shaped like a tin-tack, in the fistula opening so that the saccule is punctured each time it seals and subsequently distends again, a procedure which they term automatic repetitive decompression of the saccule. Frequently, though, the dilated terminal end of the cochlear duct, and not the saccule, is attached to the stapes base which might provide an anatomical explanation for differences in results on different patients. Moreover, the tack sacculotomy may itself produce a Ménière's syndrome due to the creation of a perilymph fistula (Pulec, 1969). Furthermore, the histopathological picture of endolymphatic hydrops is the end-result and not the cause of Ménière's disorder (Neumann,

Goldman (1962) reported that 17 ketosteroid production is low in people with Ménière s disorder and that 90% of such patients show good response to injections of whole adrenal cortical extract but not to corticotrophin which Maggio Perella & De Vita (1957) had previously found to be effective If Ménière s disorder is a psychosomatic disorder as Fowler & Zeckel (1952) and others contend or a manifestation of the adaptation syndrome then there should be a response to corticotrophin (Groen, 1955) Of the two principal types of cortical steroids, i e the glucocorticoids and the mineralocorticoids, there have been reports not only of the effectiveness of the glucocorticoids (Hauser 1959 Hirata 1963) but also claims for the administration of the mineralocorticoids (Naftalin & Harrison 1961) However according to Schayer s (1964) hypothesis, glucocorticoids, which previously had been shown to have a vasoconstrictor action by Ashton and Cook (1952) moderate the dilator action of histamine Thus, in the sense that histamine and the glucocorticoids are essentially antagonistic in their action on the microcirculation one would expect only one (if any) to be therapeutically effective in a microcirculatory disorder and the other compound to actually exacerbate symptoms. The influence of ACTH on patients with Ménière s disorder is, however complicated by the recent demonstration by Gejrot, Fluur & Levi (1966) that patients with Ménière s disorder along with other individuals who have sustained labyrinthine damage react differently to psychological stress.

We have previously mentioned the effect of psychotropic drugs in ameliorating the symptoms in Ménière s disorder Of the more specific vestibular suppressives those of the phenothiazine group e g cinnarizine and prochlorperazine appear to be the most effective In this section on depression of vestibular response" we can for purposes of classification, include both administration of streptomycin and vestibular neurotomy since both these procedures interrupt the flow of afferent impulses which signal to the brain the episodic disturbances of labyrinthine function The use of streptomycin depends on the specific vestibulo-toxic action of this antibiotic (Fowler 1948 Hamberger Hyden & Koch 1949 Graybiel Schuknecht Fregly Miller & McLeod, 1967 Schuknecht, 1957) The drug is given in a dose of 1 g three times a day and its effect is monitored by daily caloric tests. The response of the affected ear or the more seriously affected ear if the condition is bilateral disappears first when treatment should be stopped Unfortunately compensation of equilibrium is less perfect with older patients In any case compensation is never complete and all patients persist in having difficulty in walking in the dark (Graybiel et al. 1967) The use of the drug should therefore be confined to patients under the age of fifty years, where both ears are involved and where there has been no response to other medical treatment and where the patient refuses to undergo operation

Vestibular neurotomy has now been used for over forty years and of the 278 cases operated on by Dandy Green (1959) reported that the vertigo was relieved or improved in 95% of cases but in nearly two-thirds of the cases, the hearing got worse, and in 14% of cases the patient "eventually became deaf" Tinnitus was reported relieved in 50% of cases. However other series of cases have shown less success (Putnam 1938 Walsh & Adson 1940). A Canadian series showed that although the immediate results were good the final results were usually disappointing (Ireland 1949) In many cases the hearing has continued to fall away Moreover it should be remembered that this entails an intracranial operation which is not without risk The risk however may be slight Only two of Dandy s patients died and here the death was due to meningitis which would now be expected to respond to current methods of treatment

Even before Hallpike & Cairns (1938) had demonstrated endolymphatic hydrops as the histological correlate of Ménière s disorder

Mygind (1926) had suggested that alterations in body fluids may play a part in the pathogenesis of Ménière's disorder. There are individual patients whose episodes of vertigo respond to salt and fluid restriction and, using a double-blind technique, Klockhoff & Lindblom (1966) showed that hydrochlorothiazide is beneficial with respect to the hearing loss, vertigo and general condition in Ménière's disorder. The modus operandi for water and salt depletion procedures is uncertain since Perlman, Goldmg & Cales (1953) failed to demonstrate any consistent effect by either water depletion and loading or salt depletion and loading in cases of Ménière's disorder. Harrison & Naftalin (1968) have shown that the acute attacks of vertigo occur during a phase of sodium diuresis concomitant with a water gain.

A century ago, Knapp (1871) suggested that Ménière's disorder might be analogous to glaucoma and the symptoms be due to increased intralabyrinthine fluid pressure. Portmann, Sr (1927) followed up this suggestion 55 years later by treating Ménière's disorder by making an opening into the endolymphatic sac. He subsequently performed 60 operations of this type over the subsequent 38 years. In this series, the vertigo was relieved in 93% of cases and the tinnitus and the hearing improved each in about one-third of cases. Thus, so far as the vertigo and the hearing are concerned, Portmann obtained better results than House (1965) obtained for his 243 cases treated with the subarachnoid endolympathic shunt operation, where the vertigo was said to be improved in three-quarters of the cases and the hearing in 10% only. It is therefore not surprising that Portmann, Jr (1969) should say: It seems useless to place a tube in the arachnoidal spaces as proposed by House—a simple opening is sufficient to provoke improvement. Moreover, Shambaugh (1966) found that he could obtain the same results with simple exposure of the sac. With such a dummy operation, what could have been better as a control trial to assess the results of the subarachnoid endolymphatic shunt operation? Furthermore, 3 years later Shambaugh (1969) wrote: My initial enthusiasm for operating upon the endolymphatic sac to improve hearing in Ménière's disorder has steadily cooled. Only once did I duplicate the dramatic success of the first case with return of normal hearing and in only two more cases was there a significant, but not great, improvement of hearing. In all the rest, i.e. 92 per cent of cases, the hearing was unchanged or worse. Insertion of the "teflon" film did not give any better results in my hands than simple decompression. The operation may be complicated by otitic hydrocephalus or meningitis, so that it is not free from hazard. A simpler method of depressing the membranous labyrinth has been devised by Fick (1964), who perforates the centre of the stapes base with a needle. This opening is then enlarged to 1 mm with a burr, more fluid drawn out of the labyrinth, and the mucosa replaced. Although the earlier results for this operation were reported to be very good (relief of vertigo in 90% of cases and improvement in hearing in [illegible] of cases) the late results have been less good. As Portmann (1969) pointed out, the results obtained by other surgeons who experimented with the procedure are bad and deafness is frequent following the operation. Cody, Simonton & Hallberg (1967) have endeavoured, ingeniously, to improve on this operation by inserting a small prosthesis, shaped like a tin-tack, in the fistula opening so that the saccule is punctured each time it seals and subsequently distends again, a procedure which they term automatic repetitive decompression of the saccule. Frequently though, the dilated terminal end of the cochlear duct, and not the saccule, is attached to the stapes base which might provide an anatomical explanation for differences in results on different patients. Moreover, the tack sacculotomy may itself produce a Ménière's syndrome due to the creation of a perilymph fistula (Pulec, 1969). Furthermore, the histopathological picture of endolymphatic hydrops is the end-result and not the cause of Ménière's disorder (Neumann,

1964) The histological picture of endolymphatic hydrops may be absent in cases where there has been clinical evidence for Ménière s disorder (Berggren 1949 Wustrow & Borkowsky 1960)

In the small percentage of cases of Ménière s disorder where medical treatment has failed and recourse must be had to surgery the hearing in the affected ear is usually so impaired that one need not attempt to conserve it Moreover there may be so much distortion and tinnitus that the patient wishes the remaining auditory function to be destroyed. In these cases, membranous labyrinthectomy (Cawthorne 1943) is the method of choice However in the few cases where intractable vertigo is unresponsive to medical treatment and yet there is useful auditory function in the involved ear then destruction of the vestibular labyrinth only may be attempted by either ultrasound (Arslan 1962 James, 1965) or cryosurgery (House 1966 Wolfson Cutt Ishiyama & Myers, 1968) Although the principle of ultrasonic therapy is based on the selective destruction of the vestibular neuroepithelium it is now thought to exert also some beneficial action on the hydrodynamics of the endolymphatic system (James, Freundlich Buller Wells & Williams 1964) There is an alteration in the electrolyte composition of the endolymph The potassium concentrate is reduced and the sodium is increased Shrinkage of both the utricle and saccule have been observed suggesting a reduction in endolymph pressure House (1969) thinks that ultrasound might destroy the membranous labyrinthine wall producing an otic-periotic fistula

Using a 3 megacycle cone having a maximum power output of 22 watts per cm² Angell James (1969) has been able to stop the vertigo in 85% of a series of more than 200 cases, and the tinnitus in 30% of these cases. The hearing was impaired by 10 dB or more in 44% of cases, including complete loss in 2% Thus, as Angell James himself points out there can be few other surgical measures that can offer such a satisfactory prospect for these unhappy patients. A facial palsy occurred in under 1% of cases and in no individual was this permanent.

Some Reflections on a "Histamine Hypothesis"

In view of the confirmed demonstration that an oral histamine analogue has a beneficial effect upon Ménière s disorder it behoves us to consider whether some of the diverse features of Ménière s disorder might not be explained on a histamine hypothesis. There are fifteen features that I would wish to consider

(1) There is evidence that Ménière s disorder is a psychosomatic one (Fowler & Zeckel, 1952 1953 Ceroni & Franzoni 1963 Jongkees, 1963 Siirala, Siitala & Lumio 1965 Hinchcliffe 1967 *a*)

(2) There is a connection between migraine and Ménière s disorder (Matzdorff 1936 Atkinson 1962 Hinchcliffe 1967 *b*)

(3) Gastro-duodenal lesions may be associated with Ménière s disorder including the simultaneous occurrence of exacerbations (Wyburn Mason 1959)

(4) There may be pre-existing or co-existing internal ear pathology other than hydrops.

(5) The average duration in between episodes of vertigo is one week

(6) Stimulation of the sympathetic nervous system may produce changes suggestive of Ménière s disorder (Seymour & Tappin 1953)

(7) Acute attacks are associated with an increase in the plasma potassium concentration (Talbott & Brown 1940 Clayton Birch & Hughes 1962)

(8) Anti-histamines, e g promethazine may give prompt and persisting relief (Korkis, 1958)

(9) As well as promethazine other phenothiazine drugs which exhibit less anti histamine activity provide relief from symptoms in Ménière s disorder e.g. prochlorperazine and cinnarizine

(10) Haloperidol has been reported to cause complete disappearance of vertiginous attacks in Ménière s disorder (Cunego & Citterio 1963)

(11) Ménière's disorder responds to the anti-motion sickness drugs, such as dimenhydrinate.

(12) Some patients respond to a low salt and water diet.

(13) Tonsillectomy has been reported to produce relief of symptoms.

(14) Cases of Ménière's disorder due to an allergy in particular food allergy have been reported (Clemis, 1969 Eagle, 1948).

(15) Individuals suffering from mastocytosis or myelogenous leukemia may suffer from vertigo.

A histamine effect might be suggested for each of these fifteen points, and this might provide a unifying concept specifically

(1) Emotional stress may result in histamine liberation. In the brain, the highest concentrations of histamine are found in the hypothalamus, which provides the anatomical basis for the physiological correlates of emotional activity

(2) Horton's (1941) histamine headache is now considered to be identical with periodic migrainous neuralgia, which may be considered a migraine variant. In migraine itself there is evidence for the release of serotonin, a vaso-active amine related to histamine (Sicuteri, Testi & Anselmi, 1961 Curzon, Theaker & Phillips, 1966).

(3) In experimental animals, histamine provides a potent means of producing peptic ulceration

(4) Tissue injury not only leads to the release of histamine but also stimulates production (Dekanski, 1945)

(5) A weekly cycle could be based on antigen-antibody reactions, as well as the suggested psychosomatic determinants. In any case there is a psychosomatic-allergy interaction. Kourilsky has reported, regarding asthmatic crises, that they were always preceded by anxieties. Suppression of the emotional stimulus suppressed the allergic manifestations. Antigen-antibody reactions release histamine.

(6) Histamine acts not only on the peripheral ganglion cells of the sympathetic system, but exerts a direct action on the central ganglion cells of the system as well (Trendelenburg, 1956).

(7) Intravenous injection of histamine in the cat produces a sharp rise in plasma potassium concentration (Macmillan & Vane, 1956)

(8) A response to anti-histamine would be plausible if Ménière's disorder were in some way due to histamine liberation.

(9) Most of the phenothiazines are histamine antagonists.

(10) Although the chemical structure of haloperidol resembles that of pethidine the pharmacological activity is similar to the piperazine substituted phenothiazines.

(11) Although the anti-motion sickness effect of the antihistaminics is said to be unrelated to histamine antagonism, it may well, in fact, be due to this antagonism, but reflecting the specificity of "histamine receptors" in the central nervous system.

(12) The "low salt and water" diet, being a cheese and protein elimination diet might also be considered to be a low histidine diet. Since histidine is a histamine-precursor such a diet should decrease the histamine in the body

(13) The histamine content of tonsils is reported to be higher than that of any other organ (Lorenz, Heitland, Werle, Schauer & Gartner 1968).

(14) The occurrence of an allergy implies an antigen-antibody reaction and this releases histamine (Humphrey & Jaques, 1953)

(15) Mastocytosis and myelogenous leukaemia are the two conditions in which there is an abnormally high production of histamine

It might therefore be contended that many phenomena associated with Ménière's disorder or Ménière's syndrome might be explained on the basis of an increased histamine production or of a sensitivity to histamine. It thus behoves us to ascertain whether we might be administering β-histine for the wrong reasons, i.e. not as a vaso-dilator but as a method of desensitising to histamine. This suggestion, however might be questioned on the grounds that

1964) The histological picture of endolymphatic hydrops may be absent in cases where there has been clinical evidence for Ménière's disorder (Berggren 1949 Wustrow & Borkowsky 1960)

In the small percentage of cases of Ménière's disorder where medical treatment has failed and recourse must be had to surgery the hearing in the affected ear is usually so impaired that one need not attempt to conserve it Moreover there may be so much distortion and tinnitus that the patient wishes the remaining auditory function to be destroyed In these cases, membranous labyrinthectomy (Cawthorne, 1943) is the method of choice However in the few cases where intractable vertigo is unresponsive to medical treatment and yet there is useful auditory function in the involved ear then destruction of the vestibular labyrinth only may be attempted by either ultrasound (Arslan 1962 James, 1965) or cryosurgery (House 1966 Wolfson, Cutt, Ishiyama & Myers, 1968) Although the principle of ultrasonic therapy is based on the selective destruction of the vestibular neuro-epithelium it is now thought to exert also some beneficial action on the hydrodynamics of the endolymphatic system (James, Freundlich Buller Wells & Williams, 1964) There is an alteration in the electrolyte composition of the endolymph The potassium concentrate is reduced and the sodium is increased. Shrinkage of both the utricle and saccule have been observed suggesting a reduction in endolymph pressure House (1969) thinks that ultrasound might destroy the membranous labyrinthine wall producing an otic-periotic fistula.

Using a 3 megacycle cone having a maximum power output of 22 watts per cm² Angell James (1969) has been able to stop the vertigo in 85% of a series of more than 200 cases, and the tinnitus in 30% of these cases. tolerance to histamine is said not to increase even after prolonged courses of desensitisation (Wells, Gray & Dragstedt 1941 Feinberg 1946) Perhaps this may apply only to certain physiological effects of histamine and not those to a susceptible or damaged organ in this case the ear Although there is evidence that it is a more generalised disorder the thesis of Locus minoris resistentiae is suggested to explain the apparent localisation of Ménière s disorder in the ear

Nahm, Raynaud' phenomenon and acrocyanosis (in the women) were common. In addition in most of the patients there seemed clear evidence to support Hinchcliffe (1967 b, c) that psycho-somatic factors play a part in the aetiology of this condition

I each case the hearing loss was purely neuro-sensory in type, was associated with positiv recruitment, with relatively good speech reception and with completely *normal* middle ear and Eustachian tube function The attacks were not related to upper respiratory tract infection A caref l assessment of the hearing was performed both before and after treatment As it is seldom possible to alter neuro-sensory hearing loss in this or other conditions above the frequency of 1 000 Hz we decided to limit our study to the three frequencies 250 500 and 1 000 Hz which ere represented as an average decibel loss

Vestibular testing consisted of estibular analysis consisting of clinical balance tests, positional tests, optokinetic tests, caloric tests, nd a full series of acceleratory and deceleratory rotation tests. The findings in all cases were consistent with the auditory localisation findings and followed the pattern which e expect in case of Ménière's disease Thus clinical balance was normal between attacks, and positional test ere negative Optokinetic nystagmus was symmetrical and normal except in those cases where there as definite preponderance to one side I these cases the optokinetic nystagmus showed slight preponderance in the same direction Caloric tests gave typical Ménière-like reactions and rotation tests gav the reduced amplitude rather constant speed nystagmus hich will be describing in greater detail elsewhere

For the purpose of this study however w have limited our enquiry into the effect of betahistine hydrochloride upon hree pure tone hearing levels and upon the nystagmus recorded from *three* different rates of acceleration and *one* rate of deceleration The former consist of 1 sec² 3 sec and 6 /sec² and the latter 90° sec²

The acceleration tests provide 90 sec of stimulus recording time in the 1 sec² test, 30 sec stimulus recording time in the 3 sec² test 15 sec stimulus recording time in the 6 sec² test and in the 90° sec² deceleration test the nystagmus is a post stimulatory effect, and usually lasts for approximately 40 sec ith the nystagmus steadily declining from onset to the end of reaction

The acceleratory and deceleratory tests are performed to both right and left giving a total of 6 accelerations and 2 decelerations to be studied The paper speed used has been 1 25 cm sec and pen deflections hav been previously calibrated to known eye movements

The assessment is based upon the eye shift in degrees per second related to each stimulus and this assessment has been made both before and after completing treatment for each individual stimulus

Ey shift in degrees per second is calculated by measuring the sum of the quick phase pen movements during measured period and dividing by the time. Pen movement is measured in millimetres and calibration is such that 10 mm is equivalent to 10° eye movement (method similar to Listhlcam & Churchill, 1968) in assessing caloric ystagmus.

In the acceleratory tests we have considered the eye shift per second in the first 15 sec following the stimulus. T detect differences inherent in an increased latency period (start-lag) we have subdivided this into two periods of 1 5 sec and 6-15 sec inclush As these tw estimations are done on 3 clock ise and 3 anti clockwise rotations we have a total of 12 calculations for each set of acceleratory rotation tests per subject.

In the 2 deceleratory tests the calculation has been confined to the initial 5 sec only of recording (latency period is unimportant after such a powerful stimulus) so that w hav only 2 calculations per set of rotation tests per subject.

T ble I show the method adopted to study these calculations.

Drug dosage

All patients in this study after initial auditory and vestibular analysis ere given betahistine hydrochloride 8 mg t d (I 24 mg daily) for a period of 3 months N other drug as given during this period. All patients took their tablets regularly and there were no side effects. Post treatment analysis was per formed just before treatment had been completed

RESULTS

In Table II is summarised the results of treat ment on hearing. For both ears the hearing loss *after* treatment was less than before treatment but the difference although suggestive is not statistically significant as in the left ear there was a one in ten possibility that the improve ment was due to chance.

In Table III the vestibular function tests before and after treatment are summarised. It

Proceedings of the Symposium on Ménière's Syndrome Zandvoort September 3 1970

THE EFFECT OF BETAHISTINE HYDROCHLORIDE IN MÉNIÈRE'S DISEASE

T J Wilmot

From the Department of Otolaryngology Tyrone County Hospital Omagh Northern Ireland

INTRODUCTION

Objective assessment of vestibular function can only be achieved with highly sophisticated methods. It is desirable first to localise the lesion as central or peripheral and second to be able to measure function in an accurate and repeatable manner

For the localisation of lesions affecting balance and hearing a system of auditory analysis is essential Pure tone audiometry is used to assess the thresholds of air and bone conduction hearing to measure the loudness discomfort level, to perform the Fowler's binaural loudness balance test (if appropriate) to register the SISI scores, to measure tone decay and to show the difference between the cochlear response to interrupted and continuous tones. These measures will confirm the presence of neuro-sensory deafness and will determine the degree of pure tone loss of hearing the presence or absence of recruitment and will give a definite indication as to whether the hearing loss is cochlear or retrocochlear

Speech audiometry should give results consistent with the pure tone findings Where recruitment is present it is common to find relatively good speech perception with adequate amplification Where recruitment is absent and there is excessive pure tone decay speech discrimination is very poor

In a case where the middle ear and Eustachian tube function is suspect acoustic impedance audiometry will clarify the position and help to differentiate the relative importance of the conductive and neuro-sensory components present in the total hearing loss.

We have therefore in all these measures, the ability to localise with some accuracy the site of the lesion affecting hearing We can also assume in the vast majority of cases that the vestibular lesion is likely to be peripheral or central in keeping with the cochlear lesion.

Our next task is to establish reliable and repeatable vestibular function tests and to portray the results of these tests in a representative and statistically significant manner

Our equipment and testing methods have been described previously (Dittrich & Allen 1965 Dittrich & Wilmot 1965 Wilmot & Allen 1965 Wilmot 1966) In our latest communication (Wilmot, in press) we support the use of the "average eye shift per second" advocated by Linthicum & Churchill (1968) as a reliable means of representing induced nystagmic eye movements. In this paper in addition to the hearing, we have studied this factor as representative of vestibular function, in a small group of patients before and after treatment

CLINICAL MATERIAL AND METHODS

The small number of patients for this study were very carefully selected from a much larger group complaining of deafness, tinnitus and vertigo In each case they had a history of episodic rotatory vertigo tinnitus and hearing loss Nausea and vomiting with the attacks, a sensation of fullness in the ear between attacks, and an associated history of migraine chil

blains, Raynaud' phenomenon and acrocyanosis (in the women) were common. In addition in most of the patients there seemed clear evidence to support Hinchcliffe (1967 *a, b, c*) that psycho-somatic factors play a part in the aetiology of this condition.

I each case the hearing loss was purely neurosensory in type, was associated with positive recruitment, with relatively good speech reception and with completely *normal* middle ear and Eustachian tube function. The attacks were not related to upper respiratory tract infection. A careful assessment of the hearing was performed both before and after treatment. As it is seldom possible to alter neuro-sensory hearing loss in this or other conditions above the frequency of 1 000 Hz we decided to limit our study to the three frequencies 250, 500 and 1 000 Hz which are represented as an average decibel loss.

Vestibular testing consisted of vestibular analysis consisting of clinical balance tests, positional tests, optokinetic tests, caloric tests, and full series of acceleratory and deceleratory rotation tests. The findings in all cases were consistent with the auditory localisation findings and followed the pattern which expect in case of Ménière's disease. Thus clinical balance was normal between attacks, and positional tests ere negative. Optokinetic nystagmus was symmetrical and normal except in those cases where there was definite preponderance to one side. In these cases the optokinetic nystagmus showed slight preponderance in the same direction. Caloric test gave typical Ménière-like reactions and rotation tests gave the reduced amplitude rather constant speed nystagmus which will be described in greater detail elsewhere.

For the purpose of this study however we have *limited our enquiry into the effect of betahistine* hydrochloride upon *three* pure tone hearing levels and upon the nystagmus recorded from *three different* rates of acceleration and *one* rate of deceleration. The former consist of 1°/sec² 3°/sec² and 6°/sec² and the latter 90°/sec².

The acceleration tests provide 90 sec of stimulus recording time in the 1°/sec² test, 30 sec stimulus recording time in the 3°/sec² test, 15 sec stimulus recording time in the 6°/sec² test and in the 90°/sec² deceleration test the nystagmus is post stimulatory effect, and usually lasts for approximately 40 sec with the nystagmus steadily declining from onset to the end of reaction.

The acceleratory and deceleratory tests are performed to both right and left giving total of 6 accelerations and 2 decelerations to be studied. The paper speed used has been 1.25 cm/sec and pen deflections have been previously calibrated to known eye movements.

The assessment is based upon the eye shift in degrees per second related to each stimulus and this assessment has been made both before and after completing treatment for each individual stimulus.

Eye shift in degrees per second is calculated by measuring the sum of the quick phase pen movements during measured period and dividing by the time. Pen movement is measured in millimetres and calibration is such that 10 mm is equivalent to 10° eye movement (method similar to Linthicum & Churchill, 1968) in assessing caloric nystagmus.

In the acceleratory tests we have considered the eye shift per second in the first 15 sec following the stimulus. T detect differences inherent in an increased latency period (start-lag) we have subdivided this into two periods of 1–5 sec and 6–15 sec inclusive. As these estimations are done on 3 clockwise and 3 anti-clockwise rotations we have total of 12 calculations for each set of acceleratory rotation tests per subject.

I the deceleratory tests the calculation has been confined to the initial 5 sec only of recording (latency period is unimportant after such a powerful stimulus) so that we have only 2 calculations per set of rotation tests per subject.

Table I show the method adopted to study these calculations.

Drug dosage

All patients in this study after initial auditory and vestibular analysis were given betahistine hydrochloride 8 mg t.d.s. (i.e. 24 mg daily) for period of 3 months. N other drug was given during this period. All patients took their tablets regularly and there were no side effects. Post treatment analysis was performed just before treatment had been completed.

RESULTS

In Table II ■ summarised the results of treatment on hearing. For both ears the hearing loss after treatment was less than before treatment but the difference although suggestive is not statistically significant as in the left ear there was a one in ten possibility that the improvement was due to chance.

In Table III the vestibular function tests before and after treatment are summarised. It

Table II

Mean hearing level (dB)	Pre-drug			Post-drug			
	Mean	S E.	No of patients	Mean	S.E.	No. of patients	P^a
Left ear	29.5	5 6.	11	18 8	5.59	11	0.10
Right ear	15 0	8 17	11	11 8	6.84	11	>0.10

Using Wilcoxon s signal rank test.

will be seen that at all rates of acceleration and deceleration there is an increase in the mean eye shift/sec At certain rates of acceleration and with deceleration this increase is statis tically significant

Subjectively 9 out of 11 patients claimed an improvement in the symptom of vertigo and all 11 claimed reduction in tinnitus.

COMMENT

Treatment with betahistine hydrochloride (Serc) was associated with changes in the symptoms of all patients, and with changes in the vestibular function tests

Comparison of the 22 post treatment audiographs with the 22 pre treatment audiographs demonstrates that in 10 there was an improvement of hearing after treatment in 9 there was no change and in 3 the hearing deteriorated There was an overall average gain in hearing over the whole group in both ears.

Rotary stimulation produced more pronounced nystagmus following treatment than present initially In view of the reduced nystagmus commonly present to rotatory stimuli in this condition it is suggestive that betahistine hydrochloride has improved vestibular function in keeping with the subjective impression of the patients.

ACKNOWLEDGEMENTS

I wish to express my thanks to Dr Michael Flynn for supplying me with betahistine hydrochloride for clinical trial and to him and his colleagues of the Clinical Research Department, Philips-Duphar, Weesp, Holland, for their collaboration and statistical help.

The estimation of average eye shift per second was performed by Mr R. H. Allen, my Chief Technician, to his usual high standard. Mr Allen was also responsible for the audiometry and vestibular testing involved.

METABOLITES OF SERC AND INTERACTION OF SERC WITH ANTIHISTAMINES

H McKennis Jr

From the Department of Pharmacology Medical College of Virginia, Richmond Virginia USA

Serc[1] (2-(2 methylaminoethylpyridine dihydrochloride)) which is marketed in the United States under the generic name of betahistine hydrochloride first became an eagerly sought drug primarily through the efforts of Bayord T Horton of the Mayo Clinic. The compound was synthesized by Löffler in 1904 and was neglected until 1941 when Walter Hunt & Fossbinder restudied the synthesis of the com pound and compared it (Hunt & Fossbinder 1942) with a number of related pyridylalkylamines for possible sympathomimetic activity Contrary to many expectations which were based upon a review of Hartung (1931) the 2-(2-pyridyl)alkylamines in the investigated series showed a physiological activity similar to histamine and a lack of sympathomimetic activity The structural resemblances between histamine and Serc were early recognized by Fossbinder and his co-workers by comparing flat, two-dimensional representations of the molecules the similarity in structure is even more striking when molecular models are com pared

When the first commercial supplies of Serc, then known as PT 9 and related compounds became available to Horton he initiated basic pharmacological and clinical studies with these materials (Horton & Macy 1946 Horton, 1961 Horton & Von Leden 1962 Horton, 1962) Horton s interests were broad He recognized the possible beneficial effects of Serc in many disorders, including Ménière s syndrome However the main thrust of his work was to treat a peculiar unilateral type of headache called histaminic cephalgia, although it differs from the usual bilateral headache that can be induced with histamine The unilateral headache (Horton s syndrome) which often brings with it suicidal tendencies, is totally incapacitating to the patient at the height of the attacks. These can occur in the daytime or after the patient has retired The meticulous work of Horton and his collaborators over a period of years produced data on an extensive series of cases in which patients with Horton s syn drome were returned to a productive life by means of treatment with Serc.

Concurrent with the studies on Horton s headache at the Mayo Clinic preliminary observations were made on the use of Serc in a variety of vascular disorders, based upon the premise that Serc has some rather specific histamine like qualities and that much of its useful pharmacological activity resides in abi lity to increase the passage of blood through the microcirculation thus aiding in the restora tion or maintenance of normal physiological function. One chance observation, yet to be fully exploited in the treatment of one patient suffering from both Horton s syndrome and angina pectoris deals with the spectacular re covery of the patient from the incapacitating effects of both afflictions. Observations on this patient over a period of 6 months were faith fully recorded by Horton and Dathe

[1] Serc is available in some countries under the trade name Betaserc.

The long history of need for a satisfactory general regimen for the control of Ménière's syndrome created many clinical studies on the use of Serc. To date, the application to Ménière's disease has probably attracted more attention than all the other varied usages combined. Since it is the interest in Ménière's syndrome that has brought about the organization of this meeting, mention should be made of the many early clinical papers.* Papers on the program today include the work of a wide international distribution of investigators.

Our own work on the metabolism of Serc has been directed primarily towards identification of metabolites of Serc and the role of these and other compounds in controlling or terminating pharmacological responses to the parent Serc. In the recounting of some of these studies, I wish to acknowledge gratefully the collaboration of Dr Herbert Konzett, who has been serving as Visiting Professor of Pharmacology at the Medical College of Virginia, while on leave from his post at the University of Vienna. Dr Edward R. Bowman and Dr Faye J. Bowman, who incidentally are not related, have performed many of the chemical studies, while Mr Robert G. Bost diligently pursued both chemical and biological aspects of the problem.

The problem of the metabolism of Serc becomes all the more intriguing when one examines its structure (Fig. 1) in comparison with those of epinephrine, norepinephrine and histamine. From this one can easily see why at first glance, Hunt & Fosbinder originally thought that Serc might have some epinephrine-like qualities. As it turned out, Serc resembles histamine more in its physiological characteristics, and indeed the work of Baez (1969), Baez, Lorenzo & Orkin (1970), and Martinez (1972) has shown that Serc in its action in opening up the microcirculation is opposed by the constrictor effect of norepinephrine.

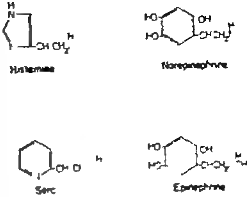

Fig. 1

Once Serc has entered the body a number of different processes, including metabolism, become available for its elimination. From chemical structural considerations, either monoamine oxidase or histaminase might be considered logical catalysts for oxidation of the side chain of Serc. Based upon the close structural resemblance between Serc and histamine, Werle and Palm (1953) studied the effect of a histaminase or diamineoxidase preparation from peas on the two compounds. As adjudged by oxygen uptake, Serc was virtually unaffected by the enzyme preparation. Additionally Serc inhibited the oxidation of histamine. Werle & Palm also showed that Serc and 2-(2-aminoethyl)pyridine (demethyl Serc) had a histamine-like action on isolated strips of gut. This effect was blocked by the antihistaminic antazoline. Latter studies showing similar effects of Serc and 2-(2-aminoethyl)pyridine on isolated strips of gut were reported by Ariëns & Simonis (1960). In our current studies on Serc, attention has been directed to possible mammalian metabolic changes in the side chain of the molecule and the possible role of these events in controlling pharmacological responses in sub-human species.

Metabolism of Serc in rabbits

Dutch female rabbits in the studies (Bowman, Bowman & McKennis, 1970 *a, b*) received 2-(2-methylaminoethyl)pyridine ("Serc base"), which was administered as a single dose (100 mg/kg). The urine was collected from animals

Metabolism of Serc in rabbits

Dutch female rabbits in the studies (Bowman, Bowman & McKennis, 1970 *a*, *b*) received 2-(2-methylaminoethyl)pyridine ("Serc base") which was administered as a single dose (100 mg/kg). The urine was collected from animals

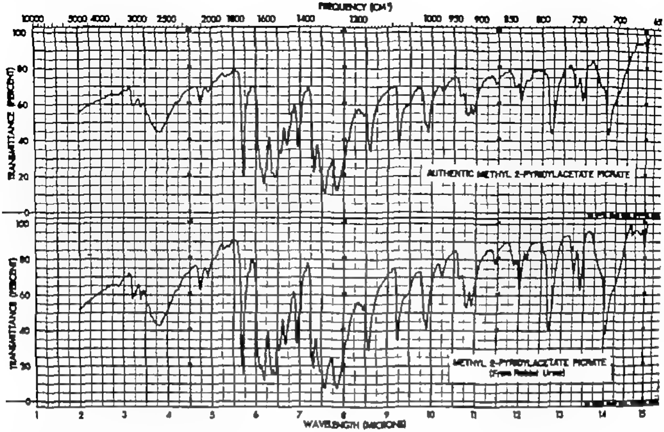

Fig 2 Comparison (in KBr pellet) of the infrared spectra of authentic methyl 2-pyridylacetate picrate and specimen prepared from 2 pyridylacetate from the metabolism of Serc.

during the subsequent 48-hour period. The method for preliminary analysis of the urine is relatively simple and depends essentially upon a separation of metabolites into groups, depending upon their acidic basic or neutral behavior

In a typical experiment with rabbits, the urine from 6 animals (approx. 2 kg each) was pooled. After clarification with diatomaceous earth the urine was passed onto a column of Dowex 50 H which retains or retards acidic and basic metabolites of Serc in which the pyridine ring is intact. The column effluent and water washes did not give a positive Koenig test for pyridine compounds and were discarded The column was then eluted with 5 N ammonium hydroxide which displaced both amphoteric and basic components, including any unchanged Serc, which might be present Previous studies with other pyridine compounds have indicated (McKennis, Turnbull & Bowman 1963) that many quaternary ammonium compounds formed by the biological N methylation of the pyridine ring can be removed from the column for later investigation by washing the column well with hydrochloric acid

A preliminary investigation of the ammoniacal eluate based upon UV absorption at 263 nm suggested that approximately 95% of the administered Serc was present in this fraction in some form or other This result was indicative of rather effective elimination of the drug by urinary excretion and led us to examine the urine further The ammoniacal solution was then placed upon a column of Dowex 21 K (OH) The effluent and water wash from this column on the basis of ultraviolet absorption and thin layer chromatography contained at the most only trace quantities of basic pyridine compounds, which *would include* unchanged Serc, and possible basic metabolites, such as 2 pyridylethanol 2-(2-aminoethyl)pyridine and 2-pyridylacetal-

dehyde. A rather effective metabolism of Sere to other material, mainly acidic in nature, in the rabbit was thus indicated.

The Dowex 21 K (OH) column was then exhaustively washed with 2 N acetic acid. The ultraviolet absorption spectra of this solution showed a close resemblance to a solution of authentic 2-pyridylacetic acid which was processed through the resins by the procedure that was used for the experimental urine. Comparison of the spectral data with that from known quantities of 2-pyridylacetate in the region 263-264 nm, led to a calculation that the processed urine at this point contained 6.9 moles of 2-pyridylacetate, or 94 6% of the Sere that has been administered to the animals. The solution was examined by thin-layer chromatography on silica gel, using methanol chloroform (15 85) as the solvent. A single Koenig positive zone at R 0 12 corresponded in R value to that of authentic 2-pyridylacetate.[a]

Additional confirmation of the presence of 2-pyridylacetate was achieved by converting the residual acids to methyl esters by treatment with methanol-sulfuric acid (Konzett, Bost Bowman, Bowman & McKennis, 1971) The methyl ester fraction was treated with picric acid to obtain the picric acid salt of methyl 2-pyridylacetate, m p 143–145 (undepressed by admixture with authentic material). Analysis, calculated for $C_{14}H_{12}N_4O_9$ [380.3], C 44 2 H 3 18 N 14 73 Found C 44 1 H 3 09 N 14 58. The product cochromatographed with authentic material in Solvent K (McKennis, Turnbull & Bowman, 1964) and showed an infrared absorption spectra (Fig. 2) in good agreement with authentic material

Although no precise information is available on the enzymes responsible for the metabolic degradation of Sere in mammals, hypothetical routes in the metabolism of the compound (Fig. 3) can be constructed from studies on analogous substances. If monoamine oxid-

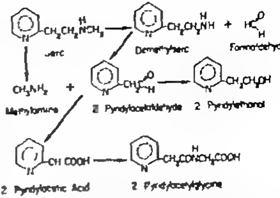

Fig 3 Abridged hypothetical metabolic scheme for metabolic alteration of the side chain of Sere.

ase is the prevailing enzyme in initial oxidation of the side chain, 2-pyridylacetaldehyde and methylamine can be expected as products. An oxidative removal of the N-methyl group of Sere would provide 2-(2-aminoethyl)pyridine and provide formaldehyde which is capable of entering one-carbon pools. Further oxidation of 2-(2-aminoethyl)pyridine would form an alternate route to 2-pyridylacetaldehyde. Oxidation of this aldehyde would provide 2-pyridylacetate. Conversely a reduction of 2 pyridylacetaldehyde would yield 2-pyridylethanol. There is already evidence (Burns, Duncan & Scales, 1967) that 2-pyridylethanol can be metabolized to 2-pyridylacetate From the information then available consideration was given to the possibility that all of the compounds shown in Fig. 3 might play a part in controlling or terminating the characteristic effects of Sere on the microcirculation.

Effect of Sere on vascular resistance

Prior to our studies on the effects of Sere and related compounds in vascular resistance, Allison & Barnes (1972) initiated a series of investigations pointing to beneficial effects of Sere in treating certain peripheral vascular diseases in man. Segel ([illegible]) has provided data showing increases in cerebral circulation following administration of Sere in man. Sipp & Snow (1949) noted that Sere brought about increased cochlear blood flow in the guinea pig. Anderson & Kubicek ([illegible]) found that

[a] Dr H Holmen-Christensen (private communication) has kindly informed us of chromatographic evidence for the metabolism of Sere to 2 (2-aminoethyl)pyridine and pyridylacetate in man.

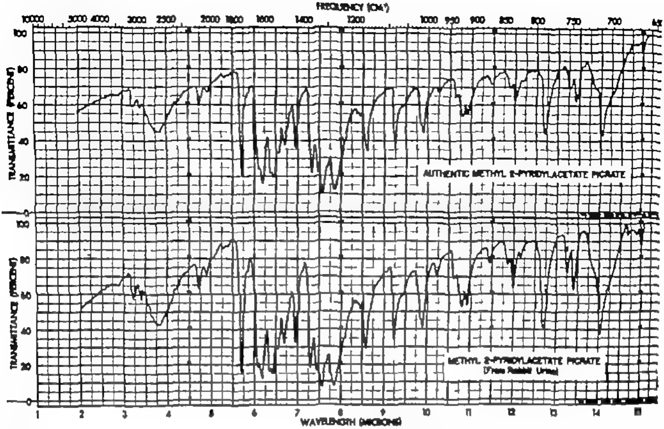

Fig 2 Comparison (in KBr pellet) of the infrared spectra of authentic methyl 2 pyridylacetate picrate and specimen prepared from 2 pyridylacetate from the metabolism of Serc.

during the subsequent 48-hour period. The method for preliminary analysis of the urine is relatively simple and depends essentially upon a separation of metabolites into groups, depending upon their acidic, basic, or neutral behavior

In a typical experiment with rabbits, the urine from [illegible] animals (approx 2 kg each) was pooled After clarification with diatomaceous earth the urine was passed onto a column of Dowex 50 H [illegible] which retains or retards acidic and basic metabolites of Serc in which the pyridine ring is intact The column effluent and water washes did not give a positive Koenig test for pyridine compounds and were discarded The column was then eluted with 5 N ammonium hydroxide, which displaced both amphoteric and basic components, including any unchanged Serc, which might be present. Previous studies with other pyridine compounds have indicated (McKennis, Turnbull & Bowman 1963) that many quaternary ammonium compounds formed by the biological N methylation of the pyridine ring can be removed from the column for later investigation by washing the column well with hydrochloric acid.

A preliminary investigation of the ammoniacal eluate based upon UV absorption at 263 nm suggested that approximately 95% of the administered Serc was present in this fraction in some form or other This result was indicative of rather effective elimination of the drug by urinary excretion and led us to examine the urine further The ammoniacal solution was then placed upon a column of Dowex 21 K (OH) The effluent and water wash from this column on the basis of ultraviolet absorption and thin layer chromatography contained at the most only trace quantities of basic pyridine compounds which would include unchanged Serc, and possible basic metabolites, such as 2 pyridylethanol 2-(2-aminoethyl)pyridine and 2 pyridylacetal

and comparison of infrared spectra with an authentic sample.

Although the ultraviolet absorption assay of the acidic fraction of processed urine can be used as an indicator for the presence of acidic metabolites of Serc along with other procedures, some caution must be used in interpretation. In studies on the metabolism of 2-(2 methoxyethyl)-pyridine which is metabolized via the intermediate 2-pyridylethanol to 2-pyridylacetate Burns et al. (1967) have considered the possible presence of 2-pyridylacetylglycine as a metabolite This compound in addition to possible other acidic metabolites such as a glucuronide and a sulfuric acid ester of 2-pyridylethanol would be expected, if present, to show ultraviolet absorption similar to that of 2-pyridylacetate and thus enhance the value calculated for 2-pyridylacetate.

Factors controlling the metabolism of Serc to 2-pyridylacetate

The demonstration that 2-pyridylacetate is a metabolite of Serc in the dog and the rabbit has focussed attention on the source of the enzymatic mechanism responsible for this conversion. Serc was incubated (Bowman et al., 1970 *b*) aerobically with a 12 000 *g* supernatant fraction from homogenized rabbit liver that had been fortified by addition of TPNH. By application of thin-layer chromatography and ion-exchange resins, five Koenig-positive components were separated from the incubation mixture. The ultraviolet absorption of the acidic fraction from the incubation of 1.5 µmoles of Serc with fortified homogenate at 37 for 2 hours indicated the formation of 0 11 µmoles of 2-pyridylacetate, or material with similar ultraviolet absorption characteristics

In addition to further consideration of the metabolism and elimination of Serc from man and other animals, it will be of interest to extend studies that already show a negative effect of antihistaminics on the metabolism and pharmacological effects of Serc. Werle & Palm (1953) have noted the inhibitory effect of antazoline on the ability of Serc to contract isolated strips of gut. Konzett & Bost (1970), as part of studies on the effect of Serc on peripheral vascular resistance, noted that pretreatment with chlorpheniramine served to reduce the effects of both histamine and Serc on the perfusion pressure.

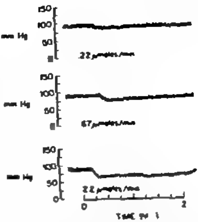

Fig 5 Effect of -(2-aminoethyl)pyridine on the ulnar artery blood pressure of the surgically prepared forelimb of th dog with blood t constant rate of flow

The use of antihistaminics concurrent with the use of Serc in human medicine although it has occurred, has not been thoroughly studied. The available information on constrictor effects of antihistaminic compounds on the microcirculation (Schayer 1963) implies that these substances under some conditions may make it more difficult for Serc to do its job effectively

ACKNOWLEDGEMENTS

Appreciation is expressed to the U.S. National Institutes of Health (NIH grant no. 1 RO1 NS00966) for support of these studies, to the Research Department of UNIMED Inc Morristown, NJ for samples of Serc, and to the Clinical Research Department of N V Philips-Duphar Weesp The Netherlands, sponsors of the Symposium on Ménière Syndrome. Mr R. W Phillips of the Department of Research and Development, the American Tobacco Company kindly determined the infrared spectra. Participation of Professor Konzett in some of the studies was made possible by a National Science Foundation Fellowship.

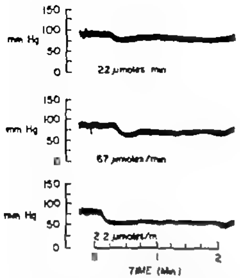

Fig 4 Effect of Serc on the ulnar artery blood pressure (*ordinate*) of the surgically prepared forelimb of the dog with blood at constant rate of flow

Serc increased blood flow through the basilar artery in the dog The experimental procedure developed by Haddy (1960) for studying peripheral vascular resistance in the forelimb of the dog was modified for our purposes and is relatively simple

With the animals under pentobarbital anesthesia and artificial respiration extracorporeal circulation was established (Konzett et al. 1971) by pumping blood at constant flow rate and 37 to the cannulated brachial artery of the right forelimb After proper tie-offs were established, pressures in the ulnar artery close and proximal to the carpus and in the accessory cephalic vein were recorded by means of a polygraph and transducers. At the beginning of the experimental period the flow of the heparinized blood was adjusted at the pump to give a nominally normal perfusion pressure at the ulnar artery Test substances were introduced into the system at a point close to cannula in the brachial artery in 0 9% sodium chloride (0 46 ml/min) Changes in ulnar artery pressure were used as a measure of vascular resistance change. When responses from Serc (Fig 4) and 2-(2-aminoethyl) pyridine (Fig 5) were compared at a dosage of 0 22 to 2.2 µmol/min for 2 min the responses (per cent change in ulnar artery pressure measured at the lowest point within 2 min after injection of the test substance) were not significantly different at the 95% confidence level ($N=5$). Under these conditions, histamine is approximately 200 times more active than Serc base, 2.2 µmoles of Serc base gave a mean percentage fall in ulnar artery pressure approximately equal to that from 0 011 µmoles of histamine base. While the recovery of preinjection pressures was almost immediate or within 1 min, after cessation of the infusion of Serc, return to preinjection pressure after administration of histamine was slower and at some of the higher dose levels (0 11–0 22 µmol/min) required as much as 10 min Pressures at the accessory cephalic vein and the carotid artery were unchanged by administration of the test substances.

2(2 hydroxyethyl)pyridine a putative metabolite of Serc, was administered at dose levels up to 22 µmol/min There were no significant changes in pressure at the ulnar artery accessory cephalic vein or carotid artery 2-pyridylacetic acid which had already been established as a metabolite of Serc in the rabbit was administered without effect on the measured pressures at doses up to 22 µmol/min

Isolation of 2 pyridylacetate as a urinary metabolite of Serc in the dog

Two male mongrel dogs were give 15 mg of Serc in aqueous solution daily by stomach tube during a period of 8 days. The urine which was initially collected over sodium fluoride, was frozen daily for subsequent processing The combined urines were processed by essentially the same procedures that have been described for the experiments on rabbits. From ultra violet absorption of the solution obtained by treating the Dowex 21 K (OH) column with acetic acid it was calculated that 1.58 g, or 45 1 of the administered Serc had been excreted as an acidic metabolite Confirmation of the presence of 2-pyridylacetic acid was achieved by esterification with methanol-sulfuric acid. The resultant methyl 2-pyridylacetate was converted to a picric acid salt and identified by melting point, mixed melting point

THE EFFECT OF SERC (BETAHISTINE HYDROCHLORIDE) ON THE CIRCULATION OF THE INNER EAR IN EXPERIMENTAL ANIMALS

INTRODUCTION

he purpose of this paper is to report on the ffect of betahistine hydrochloride (Serc) on he circulation of the spiral ligament and stria ascularis of living anesthetized guinea pigs nd chinchillas. The associated venous and rterial pressure changes are noted and dis- ussed.

This investigator reported in a previous paper (Weille Gargano, Pfister Martinez & Irwin, 1954) observations on the circulation of the spiral ligament and stria vascularis of living guinea pigs. A method for the micro- scopic observation of the blood vessels of the spiral ligament and stria vascularis was de scribed (Fig 1) Arterioles, capillaries, arterio- venous anastomosis and venules of the spiral ligament and capillaries of the stria vascularis were observed The arterioles, arteriovenous arcades, and venules possessed the ability to contract and dilate independently Intermit tence of linear blood flow was observed in arterioles, arteriovenous arcades, capillaries, and venules The rate of flow varied from time to time in each type of vessel.

The effect of anaphylactic shock upon these vessels was also previously reported from our laboratory (Weille, Martinez, Gargano Irwin, Gilchrist & Gordon, 1954). The changes noted in the blood vessels of the spiral ligament dur ing anaphylaxis included constriction of the arterioles and initial constriction followed by a dilatation of the venules of the spiral liga ment and stria vascularis. Emboli and thrombi were observed in both arterioles and venules.

In a later report (Martinez, 1965) it was demonstrated that anaphylactic shock can pro- duce endolymphatic hydrops in experimental animals (Fig. 2). The dilatation of the scala media was similar to that seen in histological sections of temporal bones of patients who had had Ménière s disease.

Hallpike & Cairns (1938), studying at post mortem the temporal bones of patients who had had clinically documented Ménière s dis- ease and who had died of unassociated factors, found gross dilatation of the endolymph sys- tem affecting chiefly the scala media of the cochlea and the saccule Lindsay in 1942 re- ported the pathological findings of a patient who had severe deafness of sensorineural type accompanied by tinnitus but not vertigo Marked dilatation of the cochlear duct was found. He concluded that labyrinth dropsy constitutes the pathological entity which may produce auditory disturbances alone or the clinical syndrome known as Ménière s disease.

A number of factors produce sensorineural deafness and vertigo One of these is an in- crease of pressure in the inner ear and more specifically in the cochlear duct, resulting in degeneration of the hearing organ. The in creased pressure of the endolymph has been explained as occurring secondary to vascular changes in the stria vascularis. Experimental

THE EFFECT OF SERC (BETAHISTINE HYDROCHLORIDE) ON THE CIRCULATION OF THE INNER EAR IN EXPERIMENTAL ANIMALS

D M. Martinez

From the Neurotology Research Laboratory Department of Otolaryngology Southwestern Medical School (University of Texas) at Dallas, Texas, USA

INTRODUCTION

The purpose of this paper is to report on the effect of betahistine hydrochloride (Serc) on the circulation of the spiral ligament and stria vascularis of living anesthetized guinea pigs and chinchillas The associated venous and arterial pressure changes are noted and discussed.

This investigator reported in a previous paper (Weille Gargano Pfister Martinez & Irwin, 1954) observations on the circulation of the spiral ligament and stria vascularis of living guinea pigs A method for the microscopic observation of the blood vessels of the spiral ligament and stria vascularis was described (Fig. 1) Arterioles, capillaries, arteriovenous anastomosis and venules of the spiral ligament and capillaries of the stria vascularis were observed The arterioles, arteriovenous arcades, and venules possessed the ability to contract and dilate independently Intermittence of linear blood flow was observed in arterioles, arteriovenous arcades, capillaries, and venules The rate of flow varied from time to time in each type of vessel

The effect of anaphylactic shock upon these vessels was also previously reported from our laboratory (Weille, Martinez, Gargano Irwin, Gilchrist & Gordon, 1954) The changes noted in the blood vessels of the spiral ligament during anaphylaxis included constriction of the arterioles and initial constriction followed by a dilatation of the venules of the spiral ligament and stria vascularis. Emboli and thrombi were observed in both arterioles and venules.

In a later report (Martinez, 1965) it was demonstrated that anaphylactic shock can produce endolymphatic hydrops in experimental animals (Fig. 2). The dilatation of the scala media was similar to that seen in histological sections of temporal bones of patients who had had Ménière s disease.

Hallpike & Cairns (1938) studying at post mortem the temporal bones of patients who had had clinically documented Ménière s disease and who had died of unassociated factors, found gross dilatation of the endolymph system affecting chiefly the scala media of the cochlea and the saccule. Lindsay in 1942 reported the pathological findings of a patient who had severe deafness of sensorineural type accompanied by tinnitus but not vertigo. Marked dilatation of the cochlear duct was found. He concluded that labyrinth dropsy constitutes the pathological entity which may produce auditory disturbances alone or the clinical syndrome known as Ménière s disease.

A number of factors produce sensorineural deafness and vertigo One of these is an increase of pressure in the inner ear and more specifically in the cochlear duct, resulting in degeneration of the hearing organ. The increased pressure of the endolymph has been explained as occurring secondary to vascular changes in the stria vascularis. Experimental

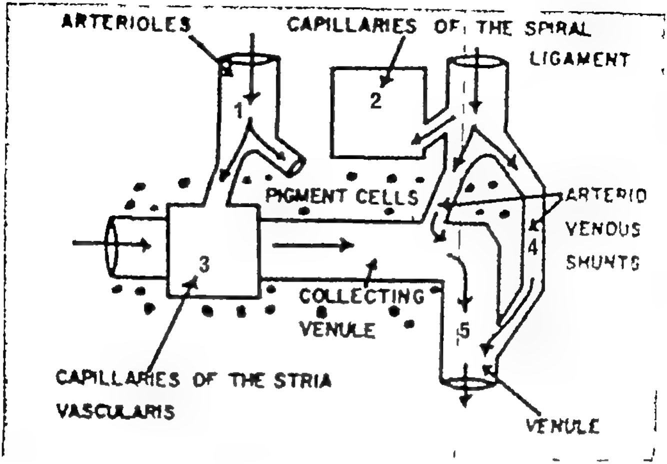

Fig 1 Diagram of the capillary circulation of stria vascularis in the guinea pig *1* arterial *2* network of the spiral ligament *3* network of the stria vascularis *4* arterial venous anastomosis, *5* collecting venule

evidence supports the fact that the endolymph is produced, for the most part, by this structure Allergic reactions or other factors affecting the capillary vessels of the stria vascularis producing a sustained vessel constriction has been considered as a cause for increasing the pressure in the endolymph (Fig 3)

This series of experiments was undertaken to determine the possible changes occurring in the capillaries of the stria vascularis and spiral ligament under the effect of betahistine hydrochloride

METHOD

Over 150 experiments were performed utilizing guinea pigs and chinchillas (Fig 4) The weights varied from 00 to 600 g for the guinea pigs and from 400 to 600 g for the chinchillas. These experimental animals were chosen because of their relative small size and because their cochleas could be made surgically accessible for this type of experiment. The technic has been reported in the previous publications quoted

Each animal was anesthetized by the interperitoneal injection of sodium phenobarbital 45 ml/kg of body weight Additional doses were administered as required during the course of the experiment.

The operative procedure consisted of five stages (1) tracheotomy (2) macroscopic exposure of the cochlea, (3) microscopic fenestration of the second or third turn of the cochlea over the scala media (4) observations of normal circulation and (5) application of betahistine hydrochloride topically intravenously and intragastrically through a plastic feeding tube Each of these steps is discussed in detail.

Tracheotomy

Oxygen was administered via endotracheal tube throughout the experiment Frequent PO_2 and PCO_2 determinations were made to ensure that normal levels were maintained

Macroscopic exposure of th cochlea

The cochlea was exposed by post-auricular incision and partial removal of the mastoid bulla (Fig. 5)

Microscopic dissection

The exposure of spiral ligament and the stria vascularis were made with a microdrill suported by a micro-

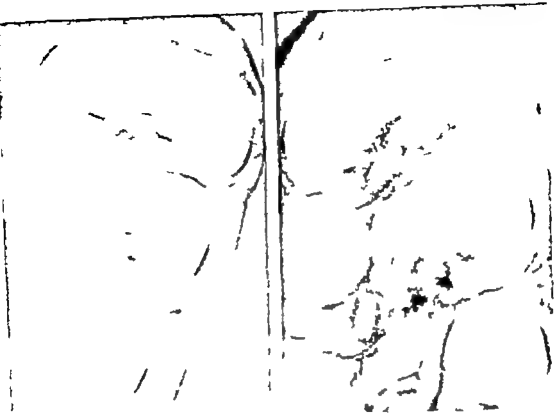

Fig 2 Temporal bone cross-section showing dilatation of the scala media of the guinea pig with artificially induced hydrops by an anaphylactic shock.

manipulator (Fig 6) The preparation was kept at a constant temperature by means of mammalian Ringer solution at 37°C flowing gently on the cochlea. Light to visualize the cochlea was provided by a 1 000 W projection bulb and transmitted via fiber-optic rod. In order to avoid trauma, exposure of the spiral ligament was made by means of polishing burr The operator circumscribed an area of bone measuring 1 mm in the horizontal plane and 0.5 mm in the vertical plane of the cochlear base. The bone was thinned down to the endosteum The circumscribed area plus the underlying endosteum were then raised gently and removed with microsurgical pick. Bone chips were thus avoided and clean sharp edges of

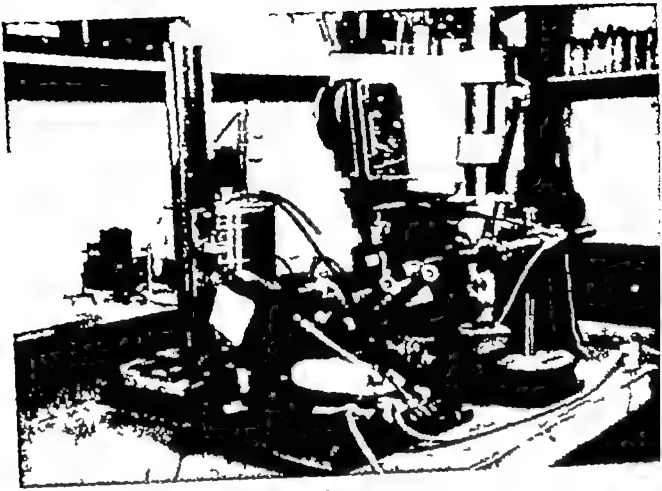

Fig 4 Experiment in progress for the study of the capillary circulation of the stria vascularis with the use of betahistine hydrochloride.

Fig 5 Cochlea expose

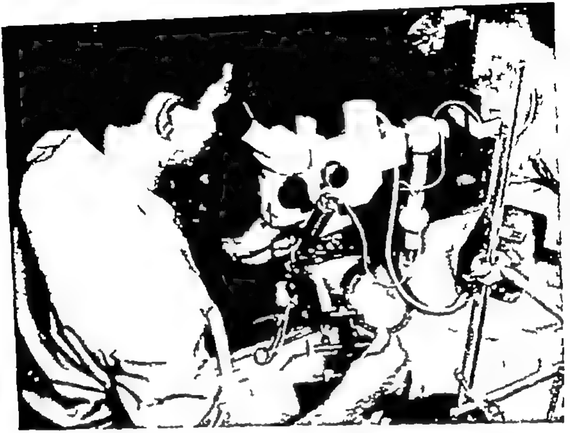

Fig 6 Fenestration of the cochlea

the fenestra were obtained Observations were made with 15 ocular and 11 ultrapack objective During the course of the microscopic exposure of the cochlea, the stapes was left undisturbed.

The location of the stria vascularis was made by determining an area located by the two bone portions that separate cochlear turn where the pigment of the stria vascularis shows in dark animals With added experience, albino animals were utilized in order to avoid the pigment in the stria vascularis that interferes with the visualization of the capillary vessels of the stria vascularis

The jugular veins were then exposed A cannula containing mammalian Ringer solution and heparin was placed in each jugular vein One of the cannulas was connected to monitoring equipment for venous pressure measurements, the other cannula was utilized to inject betahistine hydrochloride or other drugs when the intravenous route was explored In other experiments, the common carotid artery was cannulated for monitoring the arterial pressure

I another group of experiments, plastic catheter as inserted through the esophagus into the stomach of the animal The animal was placed on a special table constructed according to the method of Peck & Hoerr (1951) for the purpose of minimizing vibrations

4 m 50 s	Dilatation of venules to pre-injection, level
5 m	Blood flow returned to normal rate

Dilatation of arterioles, venules, and capillaries noted with this *concentration of betahistine hydrochloride. The blood* flow also increased These changes were of very short duration.

OBSERVATIONS

The initial venous and arterial pressures were recorded and the exposed blood vessels studied. The vessels studied included. arterioles, arteriovenous anastomosis, capillaries, and venules of the spiral ligament as well as the capillary network of the stria vascularis. The blood vessel had to meet *the following quali*fications to be considered in arteriole of the spiral ligament. It had to be located in the spiral ligament and had to take the shape of a cone with a direction of linear flow going from the larger end of the cone toward the smaller In general no part of any arteriole had a diameter greater than 60 μ Capillaries were of smaller diameter

The capillaries appeared in the spiral ligament as an intricate network of dividing and anastomosing tubules receiving flow from arterioles. The arteriovenous anastomoses were vessels of the spiral ligament. They started off as branches of the arterial and entered directly into a venule without intervening capillary network At no point did such an anastomosis look like a cylinder *The capillaries of the* stria vascularis were found in the area of pigment cells. These capillaries form a network of branching and anastomosis cylinders and they too emptied into the venules of the spiral ligament These venules took the form of cones with a direction of linear flow from the part of the vessel with the smaller diameter towards that with the larger diameter Some of these venules ran horizontal to the field, and these in turn ran into venules that were *perpendicular to the field.*

Application of betahistine hydrochloride

Topical application of a solution of betahistine hydrochloride (2 mg in 10 ml of mammalian Ringer solution) produced an immediate dilatation of the arterioles, an increase of arteriolar blood flow dilatation of the venules, although in lesser degree than that of the arterioles. An increase in capillaries was noted on visual examination (Table I)

The intravenous administration of betahistine hydrochloride was made in several concentrations, the lowest being 0 1 mg in 0 1 ml of Ringer solution As seen in Table II, dilatation of the arterioles and venules with increased blood flow in the spiral ligament and stria vascularis were noted as early as 45 sec after injection These changes lasted in this *experiment until 5 min post-injection Larger* doses of betahistine hydrochloride injected intravenously increased the periods of vasodilatation and of increased blood flow The prolonged vasodilatation reached an optimum with the larger doses, after which it appeared to remain the same without further increase (Tables III IV V)

The effect on the capillary circulation should not be examined alone but should be considered together with other possible changes in venous and arterial pressures. A number of experiments were done in order to demonstrate the effect of betahistine hydrochloride on the venous and arterial pressures of experimental animals.

ble III

bino guinea pig, 365.6 g
ml Nembutal injected i.p.
acheotomy performed
chlea exposed right ear
ft external jugular vein cannulated
nestra made in cochlea

jection	Time (post-injection)	Observations
2 mg (0.1 ml) Serc IV	1 m	Vasodilation of arterioles with increased speed of blood flow
	1 m 10 s	Vasodilation of venules
	3 m	Still dilated, slow down in flow of venules
	3 m 25	Vasodilation still present
	3 m 45 s	Capillaries appearing
	4 m 35 s	Vasodilation maintained
	5 m 15 s	Blood flow still increased
	6 m 30 s	Venules back to original size
	6 m 55 s	Arterioles still dilated
	8 m 20 s	One arteriovenous arcade in field which follow changes of arterioles described above
	9 m	Decreasing dilation of arterioles but still above initial size
	9 m 40 s	Smaller arterioles to stria vascularis back to original level
	10 m 50 s	Blood flow still increased in arterioles
	14 m 50 s	Arterioles decreased in size but still slightly above initial level
	15 m 20	Blood flow still above initial level
	21 m	Temperature 37.1°C
	[illegible] m	Arterioles back to initial size
0.3 mg (0.1 ml) Serc IV	1 m 20 s	Vasoconstriction of arterioles
	1 m 40	Arterioles to original size
	3 m	Increased flow in arterioles and venules and beginning dilation of arterioles
	3 m 15	Further dilation of venules
	3 m 40	Arterioles have increased 50 % in size
	4 m 35	Flow still increased in arterioles and venules
	7 m 50	Temperature 37.7°C
	9 m 40	Blood flow and arterioles back to initial level
0.5 mg (0.1 ml) Serc IV	45	Vasoconstriction of arterioles
	1 m 20	Blood flow in venules slowed
	1 m 35	Arterioles dilating
	2 m 10	Blood flow increasing
	2 m 50	Further dilation of arterioles, venules essentially unchanged
	7 m 25	Arterioles to initial level
	7 m 50	Circulation in arterioles still increased
	8 m 5	Circulation in venules to initial level

The first administration of betahistine hydrochloride in this experiment produced definite vasodilatation and increased blood flow as early as 1 min after injection. Further additions of betahistine produced an initial vasoconstriction of arterioles followed by dilatation but did not increase markedly the duration of this effect. The vasodilator effect was of about 50 % of the initial diameter of the blood vessels.

These experiments were done injecting as little as 0.2 mg of betahistine hydrochloride intravenously (Table VI). The changes of venous and arterial blood pressures were minimal. Slight changes were more evident when the dose was increased to 0.3 mg IV (Table VII). In this case, a slight increase in arterial pressure was present within 2 min following injection, after which it returned to its original level and decreased slightly for a period of about an hour. Changes were considered significant when they were more than 0.5 mmHg for venous pressure and 5 mmHg for arterial pressure in either direction. The variations in pressure appeared to be related to the concentration of the solution injected. The volume of the solvent was kept equal in all concentrations (Tables IX, X, XI).

Table IV

Albino guinea pig, 367.5 g
0.30 ml Nembutal injected i.p.
Tracheotomy performed
Left external jugular cannulated
Cochlea exposed right ear fenestration performed
1.0 mg (0 1 ml) Serc IV injected

Time (post injection)	Observation
10 s	Vasoconstriction of arterioles and venules
25 s	Vasodilatation, marked increased blood flow
1 m 15 s	Marked dilatation, neo arterioles and neo venules
2 m 20 s	Venules dilated two-fold
4 m 30 s	Capillaries dilated, arterioles also dilated two-fold
5 m 45 s	Dilatation still present in all vessels
6 m 10 s	Blood flow increased
7 m 45 s	Vasodilatation persists, increased blood flow persists
8 m 25 s	Vasodilatation still persists, increased blood flow persists
11 m 30 s	Vasodilatation persists, blood flow slowing down
15 m 50 s	Dilatation still present, blood flow slightly above normal in arterioles
16 m 40 s	Blood flow to normal in venules
22 m	Vasodilatation remains

Larger dosage (1 mg) of betahistine hydrochloride showed a very transitory vasoconstriction followed by marked vasodilatation, the latter lasting for over an hour

Table V

Chinchilla 360 g
0 40 ml Nembutal injected i.p.
Tracheotomy performed
Right external jugular cannulated
Cochlea exposed right ear fenestration performed
4 0 mg (0.1 ml) Serc IV injected

Time (post injection)	Observations
5 s	Tachypnea
39 s	Marked vasodilation of arterioles
1 m 35 s	Increased blood flow
2 m 40 s	Dilatation of capillaries, more are visible
2 m 58 s	Venules dilated
4 m 15 s	Many capillaries visible
6 m 55 s	Less noticeable dilation of venules, arterioles still dilated about two-fold
16 m 45 s	Arterioles still dilated, blood flow increased still, venules still dilated, capillaries still dilated
23 m	Arterioles 20 μ in diameter
27 m 40 s	Blood flow still increased
28 m 30 s	Arterioles still 20 μ
29 m 15 s	Capillaries appear less red, possibly larger amount of plasma than initially
29 m 30 s	Arterioles 25 μ
35 m 40 s	Capillaries are dilated, arterioles still dilated to 25 μ blood flow still increased
47 m 40 s	Capillaries still dilated, arterioles still dilated, blood flow still increased

The larger dosage of betahistine hydrochloride (4 0 mg) administered to the chinchilla produced tachypnea and marked vasodilatation and increased blood flow which lasted more than 1 h.

0.25 mg histamine IV produced a definite decrease of venous and arterial pressure.

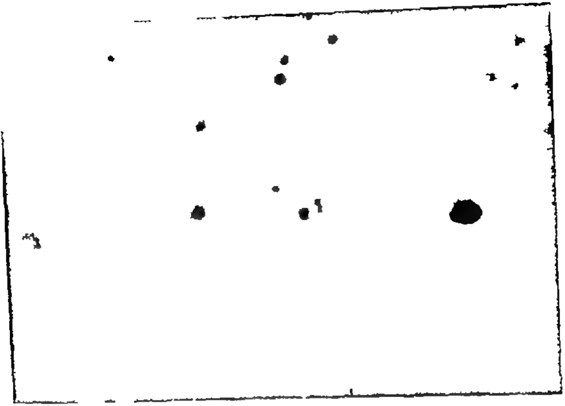

Fig. 8. Circulation of the stria vascularis after administration of intragastric betahistine hydrochloride.

SUMMARY OF RESULTS

The observation of the capillary bed of the stria vascularis after intravenous injection of betahistine hydrochloride showed changes with as little as 0.1 mg of the drug. With increased doses, the changes were more marked to an optimum level and were of longer duration. The changes seen were those of vasodilatation of the arterioles of precapillary arterioles and increased blood flow within a minute from the injection. This was followed by dilatation of the venules and capillaries. No emboli, blood sludge, or cell aggregates were observed after the injection of betahistine hydrochloride when the preparation was kept free of trauma and the temperature was kept constant. When blood sludge (primarily due to trauma) was seen prior to the administration of the drug, it often disappeared initially with the administration of betahistine hydrochloride.

During the instillation of 4 mg of betahistine hydrochloride via esophageal tube into the stomach, changes were noted in the circulation after 8 min from the instillation. These changes consisted of the dilatation of arterioles, arteriovenous arcades, and increased blood flow followed by dilatation of venules and capillaries.

In the spiral ligament and stria vascularis the increase of capillary size varied three-fold from its original level, that is, from a measurement of 10 μ to a level of 20 to 30 μ during dilatation. The speed of the blood flow in capillaries, arterioles, and venules increased on an average of 50%.

The data and results from a selected number of the experiments are shown in Tables I through XIX.

Fig 7 Circulation of the stria vascularis before administration of intragastric betahistine hydrochloride.

Control experiments were done injecting Ringer solution intravenously The changes in arterial and venous pressures were within the 10 mm range (Table VIII) In another group of experiments intravenous histamine was utilized. The changes observed were similar to those seen with betahistine hydrochloride There was an initial increase of pressure during the first minute However the post injection hypotension was more marked and prolonged. The latter was more evident during the 10 min that followed the injection (Tables XII XIII)

Betahistine hydrochloride (4 0 mg) was also administered via esophageal tube into the stomach. The initial slight increase in blood pressure was not noted until after 6 min There was then a decrease in arterial blood pressure (10 mmHg) The hypotension lasted approximately 12 min This occurred 35 min after the instillation of betahistine hydrochloride via the esophageal tube The venous pressure changes were negligible (Table XIV and Figs. 7 8)

When 12 mg of betahistine hydrochloride was administered via esophageal tube there was again a minimal initial rise of the blood pressure but the hypotension was more marked appearing 15 min following instillation. The arterial and venous pressures decreased significantly The experimental animals survived this dose (Tables XV XVI XVII XVIII)

In a comparison study the instillation of 0 4 mg of histamine was made into the stomach via esophageal gastric tube Hypotension up to 40 mmHg was noted within 8 min from the instillation of histamine. The venous pressure also decreased but less markedly (Table XIX)

0 4 mg histamine administered intragastrically via esophageal tube produced definite initial decrease of venous pressure of short duration. A decrease of longer duration was seen in arterial pressure.

DISCUSSION

In the experiments here described it was observed that betahistine hydrochloride behaves very much like histamine in its effect on the circulation of the spiral ligament and stria vascularis when administered topically and intravenously It was also demonstrated that this effect is present when administered intragastrically

ADDENDUM

In separate experiments in which an anaphylactic shock was administered to experimental animals, it was noted that those animals that were previously given intragastric or intravenous betahistine hydrochloride did not have as severe a shock and survived anaphylaxis when compared to the group not given betahistine hydrochloride where shock was more severe or the animal did not survive (Fig 9)

When the capillary circulation was observed in these experiments, it appeared that the amount of circulating sludge formation and emboli was also decreased

CONCLUSION

In conclusion our experimental studies illustrate that betahistine hydrochloride is capable of producing vasodilatation of capillaries.

g 1 Position of electrodes to record the horizontal ovements of eyes separately technique routinely used. The vertical movement is recorded for one eye only

ng middle or external ear pathology were timulated by cold air according to Dundas-Grant's technique

TECHNIQUE

(a) *Tests for the evaluation of auditory function* The following investigations were done to evaluate the effect of the medication on the auditory function 1) tonal audiometry 2) vocal audiometry 3) Békésy audiometry 4) SISI test 5) recruitment, using Fowler technique when applicable

(b) *Test for the evaluation of the vestibular function* Electrodes (Ag Ag Cl) are applied to the internal and external canthi of each eye separately (Fig 1). It must be noted, however that the horizontal nystagmus can also be recorded from both eyes together using the electrodes at both external canthi The purpose of recording each eye separately is to detect dissociated eye movements present in certain pathologies of central origin In order to obtain standardized eye recordings, we always record each eye separately Another electrode is placed above the eye, and coupled with one below the eye, to record the vertical nystagmus (Bertrand & Arbow 1966 Bertrand, 1969)

The maximum allowable impedance between two electrodes is 10 000 ohms The skin is cleaned with ether and a conductive paste is used. Calibration is regulated, so that 20° of angular eye movement produces 16 to 20 mm pen deflection. Recording is done on Schwarzer apparatus, with a paper speed of 1 cm/s, and capacitor coupling with an eight second time constant. On the horizontal plane, an eye movement to the right is recorded as an upward deflection and to the left a downward Likewise, on the vertical plane, an upward movement is recorded upward and vice-versa

Spontaneous and positional nystagmus

Spontaneous nystagmus is studied both with the eyes open and with the eyes closed When studying positional nystagmus, we used the following technique with the following positions: 1 head turned to the right, 2. head turned to the left; 3 on the right side; 4 on the left side 5 ventral 6 head hanging, 7 sitting; 8. supine. W recorded with the eyes closed for at least 30 seconds in each position.

Several criteria can be used for the analysis of spontaneous and positional nystagmus For spontaneous nystagmus, we first recorded its presence or absence with the eyes open and fixed upon small light. We do not, unless there is marked visual asym-

MÉNIÈRE'S DISEASE. SUBJECTIVE AND OBJECTIVE EVALUATION OF MEDICAL TREATMENT WITH BETAHISTINE HCl

R. A Bertrand

From the E.N.T Department Hôpital Notre-Dame Montreal Canada

AIM OF THE STUDY

Histamine is believed to have a certain value in the treatment of Ménière s disease or endolymphatic hydrops. Recently betahistine HCl was found to have certain histamine like properties.

Following the earlier reports in relation to the treatment of Ménière s disease with histamine publications concerning the effect of betahistine HCl in Ménière s disease have been presented by various authors (Hicks, Hicks & Cooley 1967 Le Pere 1967 Wolfson Myers & Schlosser 1967 Martinez, 1972)

The purpose of the present study is to evaluate not only the subjective changes but also the objective changes following drug administration in both normal and pathological subjects presenting Ménière s disease Both the cochlear and vestibular functions are analyzed and the specific aims are

1) To evaluate the effect of betahistine HCl on the function of the labyrinth in healthy volunteer subjects by comparing it to a placebo in a double blind study

2) To evaluate the effect of betahistine HCl and a placebo using a randomized double blind method for both subjective and objective effects in patients presenting Ménière s syndrome.

3) To evaluate the long term effect of betahistine HCl both for the subjective and objective results in a group of 102 patients, presenting typical Ménière s syndrome No patient presenting vertigo of other etiologies is included in this group Evaluation of the subjective symptoms as well as objective evaluation of cochlear and vestibular functions were made at different intervals during the continuance of treatment which varied from 4 months to 54 months.

4) To evaluate the presence and severity of adverse effects of betahistine HCl.

CHOICE OF SUBJECTS

In the first group the study includes 10 healthy volunteers, five males and five females, between the ages of 20 and 29 years, without history of otoneurological pathology Patients in the double-blind study as well as those in the longitudinal study include patients presenting non-equivocal Ménière s syndrome Randomization for reasons which will be discussed later on was not done There is no age restriction in this group but pregnant women were excluded.

METHODOLOGY

On all subjects both subjective and objecti[ve] modifications were studied at regular contr[ol] visits.

The objective tests included studies of bot[h] the cochlear and vestibular function Bo[th] studies of the spontaneous nystagmus, as we[ll] as positional caloric and rotational stimula[tions] were done Several patients, having n[o] response to caloric stimulation as used accord[ing] to Hallpike s technique (30 and 44) wer[e] stimulated with ice water at 0 C. Others, hav

Fig. 1 Position of electrodes to record the horizontal movements of eyes separately technique routinely used. The vertical movement is recorded for one eye only

ing middle or external ear pathology were stimulated by cold air according to Dundas-Grant's technique.

TECHNIQUE

(*a*) *Tests for the evaluation of auditory function* The following investigations were done to evaluate the effect of the medication on the auditory function 1) tonal audiometry 2) vocal audiometry 3) Békésy audiometry 4) SISI test. 5) recruitment, using Fowler technique when applicable

(*b*) *Tests for the evaluation of the vestibular function* Electrodes (Ag-Ag Cl) are applied to the internal and external canthi of each eye separately (Fig. 1) It must be noted, however that the horizontal nystagmus can also be recorded from both eyes together using the electrodes at both external canthi The purpose of recording each eye separately is to detect dissociated eye movements present in certain pathologies of central origin In order to obtain standardized eye recordings, always record each eye separately Another electrode is placed above the eye, and coupled with one below the eye, to record the vertical nystagmus (Bertrand & Arbow 1966 Bertrand, 1969).

4 731761

The maximum allowable impedance between two electrodes is 10 000 ohms The skin is cleaned with ether and a conductive paste is used. Calibration is regulated, so that 20° of angular eye movement produces 16 to 20 mm pen deflection Recording is done on Schwarzer apparatus, with paper speed of 1 cm/s, and capacitor coupling with an eight second time constant On the horizontal plane, an eye movement to the right is recorded as an upward deflection and to the left as a downward. Likewise, on the vertical plane, an upward movement is recorded upward and vice-versa

Spontaneous and positional nystagmus

Spontaneous nystagmus is studied both with the eyes open and with the eyes closed When studying positional nystagmus, w used the following technique with the following positions. 1 head turned to the right, 2. head turned to the left, 3 on the right side; 4 on the left side 5 ventral 6 head hanging, 7 sitting, 8 supine We recorded with the eyes closed for at least 30 seconds in each position.

Several criteria can be used for the analysis of spontaneous and positional nystagmus For spontaneous nystagmus, we first recorded its presence or absence with the eyes open and fixed upon a small light. W do not, unless there is marked visual asym-

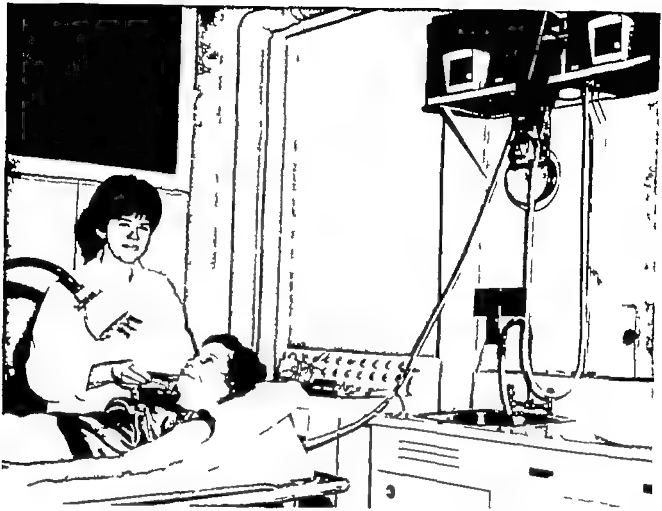

Fig 2 Caloric stimulation the patient is on a stretcher with the head flexed 30° The water in the tanks is in continuous circulation in order to keep the temperature constant at 30° and 44°C.

metry during clinical examination, record lateral gaze nystagmus. This procedure is repeated with the eyes closed, also asking the patient to keep his eyes in a central position. For positional nystagmus, we note its absence or presence If present, it is classified according to the modification of Nylen's classification made by Aschan Bergstedt & Stahle (1956)

Type I Persistent direction-changing nystagmus
Type II Persistent direction-fixed nystagmus
Type III All varieties of transitory positional nystagmus (e g. Nylen's transitory irregular transitional, paroxysmal, etc)

Caloric tests

With electrodes positioned in the same manner as for the positional nystagmus tests, caloric tests are done with the patient in a supine position, the head flexed 30° above the horizontal plane (Fig) We use the technique described by Hallpike irrigating each ear for forty seconds with water at 30° and 44°C The induced response is recorded with the eyes closed In cases of aural pathology such as tympanic perforation, the Dundas-Grant cold air technique is used. This method gives, in our opinion, a qualitative, rather than a quantitative response

The criteria used for analysis are. 1 duration of the response 2. velocity of the slow phase (VSP); 3 frequency 4 directional preponderance 5 labyrinthine preponderance.

The direction of preponderance is calculated in a percentage manner according to the formula already presented by Jongkees, using the VSP as the parameter of analysis.

The formula is as follows.

$$\frac{(1+4)-(2+3)}{1+2+3+4} \quad 100\% = \% \text{ of directional preponderance}$$

Where 1 = left ear stimulation 30°C
Where 2 = right ear stimulation 30°C
Where 3 = left ear stimulation 44°C
Where 4 = right ear stimulation 44 C

The directional preponderance is studied both for th duration and slow phase velocity parameters

The labyrinthine preponderance is also calculated i a percentage manner for the same parameters, also b the following formula, as advocated by Jongkee (1948)

$$\frac{(1+3)-(2+4)}{1+2+3+4} \quad 100\% = \% \text{ of labyrinthine preponderanc}$$

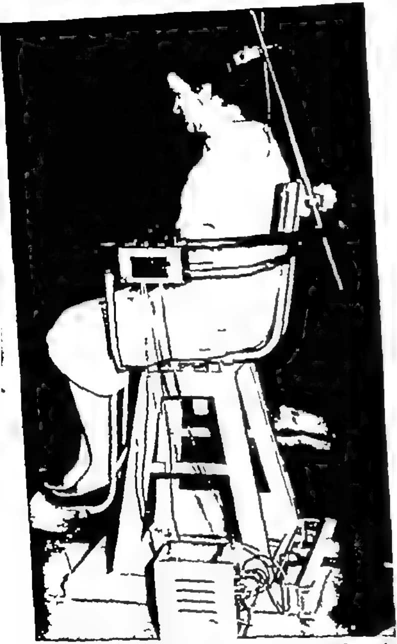

Fig 3 Rotational stimulation Controlled angular acceleration of 1 3 and 6 /s² to constant speed of 90° and sudden stop from 90°/s, for both clockwise and anticlockwise stimulations are performed at each control visit. The advantage of this stimulation is the possibility of reproducing the same exact stimulation at each control

I the evaluation of the effect of betahistine HCl in the normal and pathological subjects, the criteria used was the modification of vestibular excitability using as parameter the velocity of the slow phase

Rotation tests

Since Bárány introduced his rotation tests for the study of labyrinthine function by analysis of post-rotatory reactions, of which nystagmus was the most important, several other techniques for rotational stimulation have been proposed

Several variations of rotatory stimulation have been described since We have chosen to use that of angular acceleration. Montandon, Russbach & Pennesex (1960) introduced the study of per rotatory nystagmus, using constant acceleration and deceleration This technique

can determine the threshold of vestibular stimulation in degrees per second squared (/s²). According to *Montandon et al s definition, the threshold cor*responds to the speed per second squared which produces one nystagmic beat per second.

We proceed in the following manner with Ag-Ag-Cl *electrodes in the same position as for the positional* and caloric tests, the patient is seated in the rotating chair with his head flexed 30° (Fig 3) This gives a horizontal plane to the lateral semi-circular canal and *assures maximum stimulation* during rotation. The previous calibration of the recording sensitivity (20° eye movement = 20 mm of pen displacement) is re verified, using a Maddox cross, for both the hori zontal and vertical leads. In total darkness, and with the eyes open, four controlled rotations are done.

A counter-clockwise linear acceleration at a rate of 1 per second squared (1 /s²) is maintained until a *speed of 90° is reached After _ min of constant speed* at 90° the rotation is stopped suddenly The nystagmic response is recorded during the entire rotation and the post rotatory period. This is repeated, using a *linear acceleration. These two rotations are followed* by a counter clockwise (and then a clockwise) accelera tion of 3 /s² to a speed of 90° which is again main tained for two minutes. Deceleration is then begun *at 6 /s This technique is a slight variation of that* of Montandon et al. which accelerates and decelerates at 3 /s² and then at 6 /s² for both the counter-clock wise and clockwise rotations Montandon et al s tech *nique requires two additional rotations* which prolong the duration of the tests without in our opinion, providing additional information. In our technique, we obtain 1 /s² and 3 /s² positive acceleration stimulation *of each labyrinth as well as a sudden stop from 90°* constant speed and 6 /s² negative acceleration from both labyrinths

The parameters which we study are the following: *(a) vestibular threshold, using Montandon et al s de*finition of one nystagmic beat per second (*b*) velocity of the slow phase at stimulation of 1 3 and 6 /s² and a sudden stop

For the rotational stimulation, we used the same criteria as for the caloric stimulations to evaluate the effect of betahistine HCl, the velocity of the slow phase

DESCRIPTION OF MEDICATION

For the double-blind study of normal subjects and of Ménière s patients, the tablets were supplied by the Unimed Pharmaceutical Co Both the placebo and *the active drug* had the same appearance and were indistinguishable from one another

The *code* was made by Unimed Pharma ceutical Co , the active tablets coming from the Lot 111 641 61 the placebo tablets from the Lot 19 A 001 A The code was not broken until the double-blind studies were ended. Also the medication was given in a randomized fashion by the secretary without knowledge of the clinician as to whether the patient received the drug or the placebo.

It is to be noted that a sealed envelope containing code numbers to corresponding drugs was given to the researcher This was done in case of emergency towards a drug reaction. The need did not arise to break the code be fore the end of the study

For the patients included in the long term longitudinal study medication was supplied by Unimed Pharmaceutical Co. with the clinician cognizant of the fact that he was having active drug There was no code on this drug

Group I

Every volunteer was examined by the clinician to ascertain that he did not present any ear nose and throat pathology The ear drums were examined and found to be normal in all patients. There was no history of cranial trauma, ear infection or vertiginous symptoms in all of these healthy subjects. These subjects included 5 males and 5 females the ages vary ing from 20 to 29 years of age. *Audiometric* tests were performed on all of these subjects and were found to be normal These audiometric tests were not repeated at the end of the study in the normal subjects, as no modifications were expected.

Following a control test of the vestibular function for the study of spontaneous nystagmus and positional, caloric and rotational stimulation each subject was given a code number which corresponds to the order of his admission on the *project. Namely the first* patient accepted is given no 1 the second is given no 2, etc.

He was then given one of the two medications, either betahistine HCl or the placebo in a randomized manner and advised to take his medication The posology of two tablets *t i d. for* 1 week before his appointment as well as in the morning and noontime on the

day of his appointment. The total daily dosage was of 24 mg a day

To give more value to this normal group of subjects, all vestibular tests were made in the same period of the day as was the control test. We also advised every subject to refrain from taking alcohol during the drug-study period and to refrain from using any other concomitant drug

All of these ten normal subjects were paid for their participation in the experiment and all of them completed the experiment as scheduled

RESULTS

Group I Normal subjects

There were no modifications in this group of normal subjects with both betahistine HCl or the placebo as can be seen in the summary presented in Tables I and II.

Johnson (1969) in a personal communication dated October 2nd, 1969 stated. I have also tested Serc on normal humans and found no change in ENG from caloric stimulation.

Group II A double-blind evaluation in Ménière's patients

The original protocol included three distinct groups of subjects: (*a*) double-blind evaluation in normal subjects (*b*) double-blind evaluation in Ménière s patients and (*c*) longitudinal study in Ménière's patients.

As far as the second group is concerned in regard to the double-blind evaluation of betahistine HCl and a placebo in Ménière s patients, the protocol required a pre-treatment evaluation of the subjective and objective cochlear and vestibular function, followed by the administration in a randomized double blind manner of the placebo or drug for a period of one month, after which, following another control, a cross-over to the other medication was made for an additional month of treatment, again followed by a new control.

At the time this protocol was elaborated, the double-blind study was inserted in order to comply with rules and regulations of certain Food and Drug Administrations who suggest that double-blind studies be included in clinical trials for drugs subjected to their Department for approval in the treatment of various diseases.

However it is the author's opinion that a double-blind evaluation in patients presenting Ménière's syndrome cannot be performed adequately except under almost impossible conditions

Several reasons exist for this statement. One reason can be considered to be the presence of spontaneous remission which can occur in this symptomatology It is well known that the majority of patients can have spontaneous remission in the average of four to eight months and in certain cases for several years without any medication (Crowe, 1938 McNally & Stuart, 1955) In the author's series, *one* patient had a period of remission of 17 years.

Case history J D R., 52 year-old male

This 52-year old male consults for vertigo. I his history he states that, at the age of 10 or 1 years old, he presented objective rotatory crises with nausea and vomiting These crises were present at the

can determine the threshold of vestibular stimulation in degrees per second squared (°/s²) According to Montandon et al s definition, the threshold corresponds to the speed per second squared which produces one nystagmic beat per second

We proceed in the following manner with Ag Ag-Cl electrodes *in the same position as for the positional* and caloric tests, the patient is seated in the rotating chair with his head flexed 30° (Fig. 3) This gives a horizontal plane to the lateral semi-circular canal and assures maximum stimulation during rotation The previous calibration of the recording sensitivity (20° eye movement = 20 mm of pen displacement) is reverified using a Maddox cross, for both the horizontal and vertical leads. In total darkness, and with the eyes open, four controlled rotations are done

A counter-clockwise linear acceleration at a rate of 1° per second squared (1°/s²) is maintained until a speed of 90° is reached. After 2 min of constant speed at 90° the rotation is stopped suddenly The nystagmic *response is recorded during the entire rotation and* the post rotatory period This is repeated, using a linear acceleration These two rotations are followed by a counter clockwise (and then a clockwise) acceleration of 3°/s² to a speed of 90° which is again maintained for two minutes Deceleration is then begun at 6°/s This technique is a slight variation of that of Montandon et al. which accelerates and decelerates at 3°/s² and then at 6°/s² for both the counter-clockwise and clockwise rotations. Montandon et al. s technique requires two additional rotations which prolong the duration of the tests without, in our opinion providing additional information. In our technique, we obtain 1°/s² and 3°/s² positive acceleration stimulation of each labyrinth as well as a sudden stop from 90° constant speed and 6°/s² negative acceleration from both labyrinths

The parameters which we study are the following (*a*) vestibular threshold, using Montandon et al. s definition of one nystagmic beat per second (*b*) velocity of the slow phase at stimulation of 1 3 and 6°/s² and a sudden stop

For the rotational stimulation we used the same criteria as for the caloric stimulations to evaluate the effect of betahistine HCl the velocity of the slow phase

DESCRIPTION OF MEDICATION

For the double-blind study of normal subjects and of Ménière s patients, the tablets were supplied by the Unimed Pharmaceutical Co Both the placebo and the active drug had the same appearance and were indistinguishable from one another

The code was made by Unimed Pharmaceutical Co the active tablets coming from the Lot 111 641 61 the placebo tablets from the Lot 19 A 001 A The code was not broken until the double-blind studies were ended. Also the medication was given in a randomized fashion by the secretary without knowledge of the clinician as to whether the patient received the drug or the placebo

It is to be noted that a sealed envelope containing code numbers to corresponding drugs was given to the researcher This was done in case of emergency towards a drug reaction. The need did not arise to break the code before the end of the study

For the patients included in the long-term longitudinal study medication was supplied by Unimed Pharmaceutical Co with the clinician *cognizant of the fact that he was having active* drug There was no code on this drug

Group I

Every volunteer was examined by the clinician to ascertain that he did not present any ear nose and throat pathology The ear drums were examined and found to be normal in all patients. There was no history of cranial trauma, ear infection or vertiginous symptoms in all of these healthy subjects. These subjects included 5 males and 5 females, the ages varying from 20 to 29 years of age. Audiometric tests were performed on all of these subjects and were found to be normal These audiometric tests were not repeated at the end of the study in the normal subjects, as no modifications were expected.

Following a control test of the vestibular function for the study of spontaneous nystagmus and positional caloric and rotational stimulation each subject was given a code number which corresponds to the order of his admission on the project. Namely the first patient accepted is given no 1 the second is given no 2, etc.

He was then given one of the two medications, either betahistine HCl or the placebo in a randomized manner and advised to take his medication. The posology of two tablets t.i.d. for 1 week before his appointment as well as in the morning and noontime on the

animal experimentation of Martinez (1972) in the guinea pig, it is believed that betahistine HCl produces vasodilatation of the capillaries of the stria vascularis, probably capable of modifying the permeability of these capillaries and possibly altering the status of endolymphatic electrolytic composition and pressure. If such were the case, the administration of betahistine HCl in the first stage of a double-blind study could restore a normal endolymphatic system in the second trial period and the placebo would be equivalent to treating a normal cochleo-vestibular apparatus.

For these various reasons, we are giving no interpretation whatsoever to the double-blind evaluation in Ménière s which was initiated but not completed.

Because of the psychological aspects closely related to this syndrome, which was studied in detail in 31 patients by Basecqz (1969), we also did not feel justified to treat in a double-blind manner patients in a longitudinal study by substituting at certain periods of the treatment, the active drug with a placebo identical to the drug. Many of these patients who had previously been controlled by other medication for a certain period, either because of drug efficacy spontaneous remission absence of their own probable etiological factors, such as "stress "allergy" etc could be influenced to believe that the drug had become ineffective a phenomenon which had previously been also experienced with other drugs.

Group III Longitudinal study

In the author's opinion, the only valuable evaluation of any treatment for Ménière s disease is a longitudinal study of a long-term duration Certain premises must be taken into account Among these, must be considered spontaneous remission, lack of homogeneity various possible etiological factors, randomization, as well as the psychological aspect of this disease and the doctor/patient relationship. All the patients included in this longitudinal study consisted either of private or clinic patients treated at each visit by the same physician in order to obtain as much homogeneity of treatment evaluation as possible. Each patient treated was classified by the author according to the intensity of his pathology in three categories, I, II and III. This gradation is purely subjective, probably has no value for comparison with patients treated by other physicians, but when used by the same physician, might have some value in relation to the severity of the disease in a particular patient.

For the clinical evaluation of the Ménière's patients treated, they were divided into three groups in the following manner

I The first category is composed of patients presenting vertigo of a benign nature associated with occasional fluctuating hearing loss.

II. In this category are those patients presenting a more pronounced vertigo associated with a permanent hearing loss.

III. In a third category are included advanced cases of Ménière's disease usually not responding to medical treatment. These cases are often candidates for surgical treatment. Included in this group are all the patients referred for surgery or opinion concerning surgery by ENT colleagues or neurologists or neuro-surgeons.

The longitudinal study consists of 102 patients with ENG and audiometric controls. The patients were tested before the beginning of treatment with betahistine HCl and then submitted to the treatment, with control at 1 month, 2 months, 4 months and afterwards for the longer-term evaluation, at periods of 6 months to a year

The regular controls included for the audiometry tonal, vocal, Békésy SISI audiometric tests. The vestibular test included spontaneous and positional stimulation as already described. Caloric stimulation at 30 and 44 C or Dundas-Grant technique in the presence of drum perforation and also angular acceleration at 1 3 and 6 /s and sudden stop from 90.

First of all, before the test, the patient was seen and examined by the author the severity of his disease evaluated and the symptomatology for vertigo, nausea, vomiting, tinnitus.

quency of one every week and sometimes more often They could happen at any time in the day and even at night when he would wake up with nausea and vomiting These vertiginous episodes lasted for a period of 1 / to 2 years, with no tinnitus or hearing loss during the crises. There was a complete remission of the crises for a duration of 15 years.

At the age of .5 he suddenly started to present vertiginous crises at a frequency of 3 to 4 crises a day with nausea and vomiting. When asked how many crises he presented he answered. "Hundreds, hundreds and hundreds" During that period he was incapable of doing any work and had to lie down when he had the vertiginous crises. For a period of 3 years, his wife had to work in order to compensate for his total loss of work. There was a slight left ear hearing loss noted during that period. After 3 years, the vertiginous episodes stopped suddenly with no treatment

After a complete remission of 17 years, he again started to present tinnitus in the left ear a gradual left ear hearing loss, and a sensation of fullness or pressure in that ear Eighteen months later vertiginous crises reappeared with nausea and vomiting which were still present when he consulted. This patient presenting a characteristic syndrome of Ménière had two periods of complete remission. The first one of approximately 13 years and the second one of a duration of 17 years

A trial period of 1 month must be then considered too short a period, yet, to extend these periods to several months is almost impossible and in many cases not justifiable If for example, a trial period of 6 months was instituted it is inconceivable that a patient for the sake of scientific study should be kept on a placebo drug while presenting an uncontrollable incapacitating syndrome during all that period The clinician would be morally unjustified for not treating this patient. Moreover many of these patients, in the absence of effective control of their symptomatology would either stop taking the medication or consult elsewhere for adequate treatment.

Another aspect which would seem to invalidate most double blind studies is the absence of homogeneity of the patients treated. While the anatomo-pathological manifestations of cochleo-vestibular hydrops has been well demonstrated the etiological factors still remain in the realm of hypothesis. Several hypotheses exist which seem capable of producing this picture of hydrops. The factors capable of producing these hydrops may respond to various treatments and may explain the multiplicity of treatments as well as the variations of results obtained in certain cases in which an effective treatment in one patient might be ineffective in another

This lack of homogeneity may be present not only in relation to the etiological aspect, but also in relation to the severity of the disease in patients afflicted with this syndrome.

Another aspect which must be considered is the choice of patients to be included in this double-blind study In most cases, it is impossible to include in a randomized fashion patients presenting Ménière s syndrome Many patients may be referred or may consult for a marked incapacitating disease for which either the referring ENG neurologist or physician after having tried several available medical treatments, has convinced the patient that surgery is indicated It would be difficult to include these patients in a double blind study in a randomized manner Also certain patients, because of occupational hazards social conditions or geographical location cannot be included in a randomized fashion in a double-blind study

While this objection to a double blind study in Ménière s patients may apply in a general manner to all medications, another objection exists with the use of betahistine HCl As will be explained in the discussion following the

in the left side which went from a Type II to Type I and for the right side from a Type IV to a Type II. There is no significant change in vocal audiometry. This probably explains the subjective sensation of no improvement of hearing.

Vestibular test also demonstrates modifications of the slow phase with the medication.

This patient is now under treatment for over 4 1/2 years and was last seen 2 months ago. The vertiginous crises are now almost completely controlled and when present do not last more than 10 to 15 sec. On several occasions he stopped taking the medication. Within a few days, the vertiginous crises reappeared, only to be controlled again when this drug was re-administered.

Case history L. M. 71 year-old male, right ear Ménière's disease

This 71 year-old male was investigated for a right ear Ménière, present for the last 10 years. The vertiginous crises were frequently associated with nausea and vomiting and recently had shown a marked increase in intensity and frequency. The audiometric test (Fig. 5) showed a 50 dB neuro-sensorial loss on the right side with diminished discrimination with Type IV Békésy and a positive SISI test.

A 2 month treatment with betahistine HCl, 24 mg daily showed a marked improvement of the vertiginous problem. This patient was then seen at regular intervals for a period of up to 23 months. When seen in March '68, the patient stated that he had no more vertiginous crises. He ran short of the medication for a few weeks and the vertigo reappeared. However as soon as he resumed his treatment, the vertiginous crises again completely disappeared. There is no modification concerning the objective and subjective hearing in this patient.

Shortly after his last visit in March '68 this patient had a coronary thrombosis for which he was hospitalized in his home town and treated in an intensive manner. His cardiologist did not prescribe any betahistine HCl and after 5 or 6 days of intensive treatment, in addition to his cardiac problem, he again began to present vertiginous crises. It was only after weeks of continuous request by the patient that he should be given his "vertigo pill" that the cardiologist consented, in the presence of continuous vertiginous crises, to add betahistine HCl to the medication which this patient was already receiving for his cardiac pathology. A few days later the vertiginous crises were again completely controlled. This patient was seen a year after his coronary thrombosis, still taking betahistine HCl. He did not want under any consideration whatsoever another trial period of drug withdrawal.

Fig. 5. Audiogram of a patient for whom concomitant medication was given with betahistine HCl. The withdrawal of betahistine HCl for a few days resulted in the reappearance of vertiginous crises.

On the basis of subjective evaluation, it is almost impossible to present convincingly whether the results are satisfactory or not. Considering the group of patients who are submitted to this therapy, were we to include only those of advanced cases of Ménière's disease classified in this study as Grade III, the percentage of good results would be quite low. Yet, in some patients in whom there was a failure of other medical treatment by other ENT specialists and who were referred for surgery but were submitted to betahistine HCl therapy for a trial period, we were able to obviate the necessity of surgery and the case of such a patient is presented.

Case history L. D. 65-year-old male

This 65-year-old patient had attacks of objective rotatory vertigo which usually lasted an hour and a half for the last 18 months. They occurred at a frequency of three or four a week. Between his attacks, he also had slight equilibrium problems of a few second duration in relation to movement of his head. This is associated with a left side hearing loss and tinnitus

Fig 4 Audiogram of a patient who has been treated with betahistine HCl for over 4 / years. Several attempts at drug withdrawal were followed by reappearance of the vertiginous symptoms within a few days.

hearing sensation of fullness and headaches recorded From a subjective point of view these symptoms were graded according to their intensity for a given patient, from "0 "1" and "2 "0" being the absence of symptoms, 1" a moderate presence of the symptoms and "2" a marked presence of the symptoms. When the patients were seen these symptoms were again re-evaluated and the number was changed in relation to a given patient as to whether there was an increase or a decrease of the symptoms for that given patient The severity of the symptoms which was classified as 2" for one given patient could not be transposed as being of equal severity for another patient also classified as "2" for that symptom. An increase of a particular symptom was recorded as 3"

The results were studied for

1 The results concerning the clinical evaluation for each of the seven symptoms recorded and graded.

2. The objective modification of the audiometric tests.

3 The objective modification of the response following the various vestibular stimulations.

In our series of control tests, we have patients who have now been taking the drug for periods of over $4^{1}/_{2}$ years. One interesting aspect of the clinical symptomatology is the frequent mention by several of these long-term patients of the reappearance of the symptoms of Ménière s disease after a few days of drug withdrawal. Once they start taking the drug again, there reappears a complete disappearance of the symptoms Since we have already enunciated our disbelief of the possibility of doing a double-blind study during longitudinal studies in Ménière s patients by substituting a placebo this drug withdrawal seems to be of a significant value.

Case history J C 62 year-old male

This patient first consulted for objective rotatory vertigo with nausea and occasional vomiting. The crises were of a 10 to 15 min duration at a frequency of two to six crises per day for several months Six years previously when these symptoms were first noted the patient had a right ear tinnitus. Three years before consultation, investigation elsewhere had shown a marked neuro-sensorial hearing loss in the right ear associated with marked problems of discrimination Medical therapy previous to consultation did not control the vertiginous crises. For the last few months, he had noted an associated left sided tinnitus and hearing loss There was a 4 dB neuro-sensorial loss in the left ear

After two months of treatment, with betahistine HCl, 24 mg per day we note a marked diminution of the intensity of the crises and of their frequency The duration being of to 3 min compared with 10 to 15 min previously at a frequency of 2 to 3 crises per day The patient notes that it does not feel necessary to lay down at the time of the crises and there is also a slight diminution of the tinnitus, but no objective improvement of the hearing loss. Tonal audiometry demonstrates a marked improvement.

The pre treatment average loss of 4 dB was now 17 dB (Fig. 4). Békésy test also shows improvement

Cher docteur

À ma visite précédente (fin de mai ou juin 1968) vous m'aviez recommandé de vous revoir au bout d'une année.

Durant ce temps, j'ai pris le médicament qui améliore ma condition; lorsque je néglige de prendre ces pilules, j'ai des vertiges après quelques jours. Ma condition semble stabilisée.

Il n'y a pas de changement notable, à mon sens; aussi sera-t-il nécessaire de vous revoir? Si oui, veuillez indiquer un rendez-vous au moment qui vous convient le mieux.

Bien à vous

Fig. 7. Original letter of patient in whom the symptomatology recurs with drug withdrawal.

excitability it is to be noted that several patients showed, even following a long-term treatment, no modification of the vestibular response. Some presented from the beginning a diminution of the vestibular excitability.

For the audiometric controls as shown in Fig. 10 the improved hearing was usually of a transitory nature.

A long-term evolution is shown here for a period of 18 months, for both the vestibular and cochlear evolution in a 40-year-old female who was first referred in 1964 for bilateral Ménière and had been submitted to various treatments in the years 1964, 1965 and 1966 by the author. These included thiethylperazine (Torecan Sandoz) (Bertrand, 1966) in a double blind study and long-term evolution with no modification whatsoever of the hearing and persistence of desiquilibrium problems. She was also treated with diphenidol (Vontrol Smith, Kline & French), also with no modification whatsoever of the cochlear function and persistence of the vestibular symptomatology.

The audiogram following treatment with diphenidol was made on the 21st of June 1966, demonstrating a bilateral neuro-sensorial hearing loss, in the neighborhood of 55 dB in the left ear and 65 in the right ear. Following the beginning of treatment with betahistine HCl, there was a marked improvement in hearing which persisted for 5 months after treatment in the right ear and varied slightly in the left ear. The last audiometric control, 18 months after the beginning of treatment, demonstrates hearing improvement which did not persist consistently but is still present somewhat, especially for the left ear. This pattern of initial improvement followed by secondary stage of reversal to the pre-treatment level for the hearing function, has been frequently observed.

As can also be observed (Fig. 11) the discrimination score which was below 60% for the right ear and 75% for the left ear was improved and remained so, after eighteen months of treatment. We can compare the fact that the improvement which is noted in the discrimination score in the left ear has persisted just as the improvement in tonal audiometry whereas the right is again showing a slightly diminished discrimination score. On the same diagram, we can see for the corresponding dates the results of the Békésy audiometry which reverted from a Type II gradually to a Type I in both ears.

The vestibular evaluation for this patient which extends for a period of 3 years, demonstrates that from a hyporeflective response, we obtained an increase of the vestibular response, and after a while this response is gradually decreasing.

The same phenomena have been observed in

Fig 6 Audiogram of a patient referred for surgery by an ENT specialist in whom several medical treatments had failed to control the vertiginous attacks, and for whom surgery was obviated by medical treatment with betahistine HCl.

(Fig 6). He had been treated with several medications without improvement. This patient was referred for surgical treatment by his ENT specialist.

A trial treatment with betahistine HCl at a posology of two tablets t i d. (4 mg) was attempted for months During the first month of treatment, he noted only four attacks of vertigo of a very decreased intensity and duration. The first attack lasted about 10 min and the second one about 1 min without nausea and vomiting However he presented a concomitant problem of fatigue when reading The third attack was only of 4 or 5 min duration while the last one was of 30 min with nausea and vomiting There was also a marked decrease of tinnitus, sensation of pressure and a subjective improvement of hearing Clinically this patient who presented a very marked indication for surgery was considered sufficiently improved to continue medical treatment.

This patient has now been treated continuously with the drug for a period of 36 months. On a few occasions, he stopped taking the medication and he noticed a re-occurrence of his equilibrium problem and small vertiginous crises. These disappeared upon re-administration of the drug

On the other hand, had only patients presenting the early stages of Ménière s disease graded in Group I" by the classification used in this study be included, the results would probably be of 91 % positively cured patients, out of which a great majority could be imputed to spontaneous remission, rather than to the active drug

We must then assume that the clinical evaluation in longitudinal study can only be of an approximate certainty and only remission of long duration throughout several years with increased symptomatology following drug withdrawal, really seems to demonstrate an active effect of this drug To emphasize this point, I would like to present a letter (with its translation) from a patient who has now been taking this drug for a period of over 3 years and 8 months (Fig 7)

Many patients, as shown for a particular patient (Figs 8 *a*, *b* *c*) in the early stage presented an increase of vestibular response which we attributed, following the studies and work of Kubicek & Anderson (1967) and Martinez (1972) to a vasodilatatory effect, probably in the region of the stria vascularis which most likely modifies the permeability of the capillaries, thereby modifying the status of the endolymphatic system

While we have already discussed this modification in the early stage of the disease (Bertrand, 1967 1971) we noticed, using a long term longitudinal study with ENG control, that there appeared a second stage of hyporeflective response (Figs. 9 *a* *b*) However even though the objective response became hyporeflective in *the second stage of long term evaluation* the initial favorable results of subjective improvement usually persisted.

While several patients presented this pattern of initial vestibular response increase followed by a secondary stage of diminished vestibular

We must then assume that the clinical evaluation in longitudinal study can only be of an approximate certainty and only remission of long duration throughout several years with increased symptomatology following drug withdrawal really seems to demonstrate an active effect of this drug. To emphasize this point, I would like to present a letter (with its translation) from a patient who has now been taking this drug for a period of over 3 years and 8 months (Fig 7)

Many patients, as shown for a particular patient (Figs. 8 *a b c*) in the early stage, presented an increase of vestibular response which we attributed, following the studies and work of Kubicek & Anderson (1967) and Martinez (1972) to a vasodilatatory effect, probably in the region of the stria vascularis which most likely modifies the permeability of the capillaries, thereby modifying the status of the endolymphatic system

While we have already discussed this modification in the early stage of the disease (Bertrand 1967 1971), we noticed using a long-term longitudinal study with ENG control, that there appeared a second stage of hyporeflective response (Figs. 9 *a b*) However even though the objective response became hyporeflective in the second stage of long-term evaluation, the initial favorable results of subjective improvement usually persisted.

While several patients presented this pattern of initial vestibular response increase followed by a secondary stage of diminished vestibular

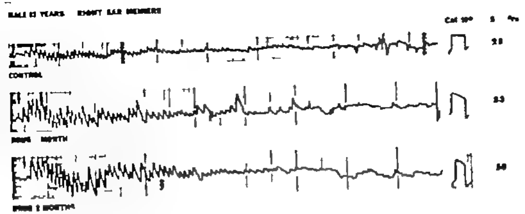

Fig 8 The increased response is also noted following sudden stop from constant speed of 90° (reproduced from *Laryngoscope* Vol. 81 p 893 June 1971)

of the cases in which it was observed. Referring again to the patient whose audiometric improvement is demonstrated in Figs 10 & 11 this patient had been treated previously because of the severity of her disease for the last three years with different drugs and had had regular audiometric controls, and at no time did we notice before the administration of betahistine HCl an improvement of hearing

SUBJECTIVE RESULTS

The subjective symptomatology was studied for the symptoms of vertigo, nausea, vomiting, tinnitus, hearing, sensation of fullness or pressure and headaches. We included in our summarized results the 62 patients who had also concomitant medication during the period of the long-term longitudinal evaluation. While these patients probably benefited from this concomitant medication, it is believed that the therapeutical effect could have been derived from the betahistine HCl The aim of our treatment was not only to evaluate betahistine HCl, but also to treat the patient. To this effect, in long-term evaluation, patients frequently are given concomitant medication, usually in the form of sedatives or tranquilizers

Added to the 40 patients for whom, to our knowledge, no other medication capable of influencing the vestibular response was administered, our long-term subjective evaluation includes an additional 62 patients, for a total of 102.

The author's gradation of patients, while subject to criticism and probably having no real scientific value, nevertheless led to some interesting conclusions, as can be seen in Table III. It is noted that patients graded as I, that is those in the early stage of the disease in whom the hearing loss is fluctuating and transitory but to be included had been demonstrated at least once by audiometry responded in a favorable manner in about 91% of the cases. Speculation can be made as to whether these patients are indeed Ménière s patients or whether they presented spontaneous remissions.

In those graded as II, there is a decrease in the favorable results, whereas in those patients graded as III by the author the results are quite different as those obtained in Group I Nevertheless, certain patients, graded as III, an example of which an audiometric test can be seen in Fig. 6 were controlled with the medication. It is to be noted that this patient as well as several others referred by ENT specialists specifically for surgery and that

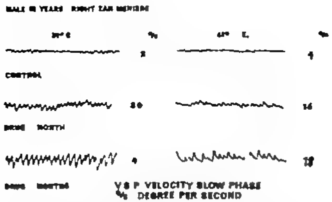

Fig 8 a Gradual increase of the intensity of the response to caloric stimulation during two months of treatment with betahistine HCl 4 mg/day (reproduced from *Laryngoscope* Vol *85* p 892, June 1971).

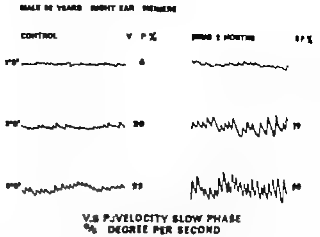

Fig 8 b Same patient as demonstrated in Fig. 1 in which an increase of response to angular accelerations of 1 3 6 /s² is present after months of treatment (reproduced from *Laryngoscope* Vol. *85* p. 893 June 1971).

the analysis of the vestibular speed of the slow phase for both ears even though one ear seems to recuperate. The vestibular speed of the slow phase shown here is the summation of the speed obtained for each ear at 1 3 and 6 /s² and that of a sudden stop from 90 There is almost a similarity of the increase of response between these two tests and the improvement of response for both the caloric and vestibular stimulations for the vestibular part of the inner ear apparatus, similar to that observed for the cochlear apparatus (Fig 12 *a b*).

While the presentation of individual patients *in Ménière s syndrome may be misleading* this marked modification of objective tests as already described can become of significant value when a larger group of patients is studied

The summation of 40 patients[1] out of 102 subjected to this study demonstrates for the caloric stimulation when dissociating right and left pathological ears and in cases of bilateral pathologies when including both pathological ears, a tendency in the early stage of an increase of the vestibular response using as criteria of analysis the average velocity speed of the slow phase in the 10 sec period of maximal response followed by a gradual decrease. The same phenomenon is observed following rotational stimulation (Fig 13) more reliability can be given to the responses obtained following rotational stimulation due to the fact that the same precise and known stimulation can be given repeatedly whereas several factors may modify the caloric stimulation

AUDIOMETRIC RESULTS

Subjective and objective modifications of the cochlear function were noted in several patients. Many patients presented as already seen in Fig 11 an objective improvement o the cochlear response but in most patients in whom this improvement was noted, it usually was of a transitory nature with the exception perhaps of the results of certain tests such as discrimination In these function tests the improvements were frequently of longer duration and in some cases are still persisting two or three years following the beginning of treatment

One of the main characteristics of Ménière s syndrome is fluctuation of hearing as already enunciated by Ménière especially in the early stage of the disease. Nevertheless, we believe that this drug could have initiated the occasional hearing improvement noted in several

[1] For this objective evaluation, patients having had concomitant medication capable of modifying th response are not included The reader is referred to Bertrand (1971) for more details.

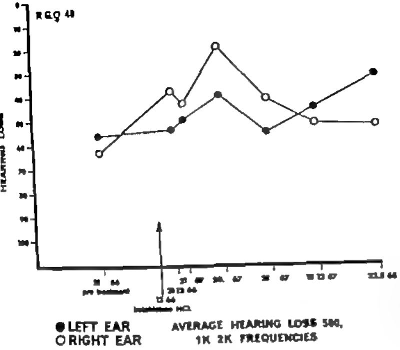

Fig. 10. Modifications of audiometric tests with betahistine HCl in a patient who had showed no modification for the last 3 years.

tients, we recommend administration prior to meals.

Two patients presented complications in the nature of a skin rash (Fig. 14 *a, b*); this disappeared following drug withdrawal. Occasionally a patient may complain of increased symptomatology usually related to an increase of the tinnitus or headache, as already discussed in the results of the subjective evaluation.

POSOLOGY

The posology in the initial stage of treatment was one tablet (4 mg) t.i.d. Because of the non-effectiveness in certain patients, an increase of the posology to two tablets t.i.d. (24 mg) was tried and this seems to us to be the more effective dosage. An example of the effect of posology variation can be seen in Fig. 15.

Certain patients who have been using this medication for two or three years will reduce their daily dosage to 16, 12 or 8 mg or proceed to complete withdrawal on their own, only to again increase the posology up to 24 mg if the symptoms recur. After several months of treatment, gradual weaning is frequently attempted, and those presenting a recurrence of the symptoms are again given medication, usually of 24 mg daily. Certain patients, as the one whose case history has been presented (J. C.) have attempted at different intervals to stop the medication only to see the symptoms reappear. This particular patient has now been taking the medication for over 4 1/2 years, has tried on several occasions to stop taking the medication, but this to no avail. The symptoms would reappear within one week and would always be controlled again after one or two weeks of treatment. He does not want to try again another period of withdrawal.

DISCUSSION

The evaluation of medical treatment of any kind for Ménière's disease is a very difficult proposition. We are faced with the problems of spontaneous remission, lack of homogeneity

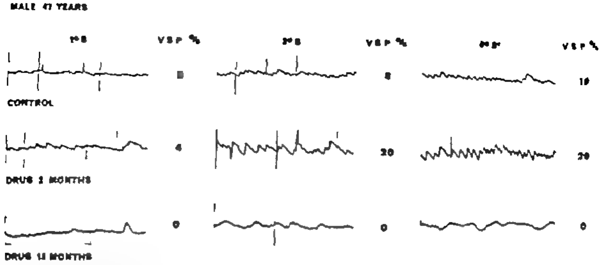

Fig 9 a Rotational stimulation at 1 3 6 /s² in a 47-year-old male presenting right ear Ménière treated with betahistine HCl, 4 mg/day the long term evaluation demonstrated that the initial increase of the vestibular response was of transitory nature.

betahistine HCl was given a pre-surgical trial and occasionally obviated the need for surgery

The results of the 102 patients for the evaluation of the various symptoms are presented in Table IV Most of the patients (24) that showed no improvement were subsequently operated Certain patients complained of increased tinnitus or headaches with the medication and such increase disappeared on drug withdrawal or reduced posology

SIDE EFFECTS

In our series, patients having gastric disorders usually were not given betahistine HCl However it was noted that patients occasionally were referred with gastric pathology and were already taking this medication with no ill effect We do not consider unless acute gastric pathology exists that it is a contra-indication to use this drug However in all of our pa

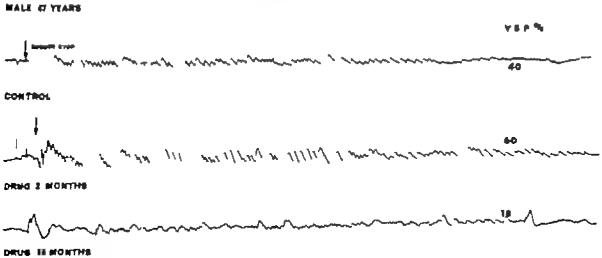

Fig 9 b The same pattern is also noted following a sudden stop from a constant velocity of 90°/s.

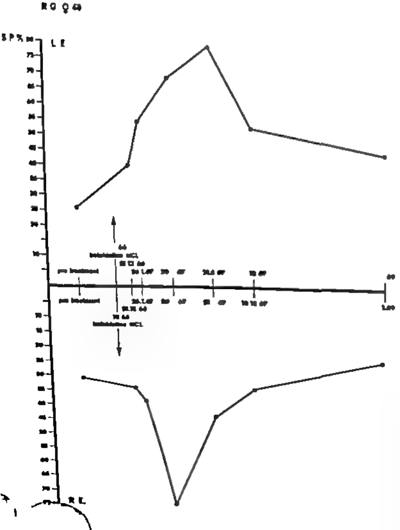

Fig. 12 b. Initial increase of vestibular response following rotational stimulation followed by a secondary stage of response decrease (reproduced from *Laryngoscope* Vol. 85 p. 894 June 1971).

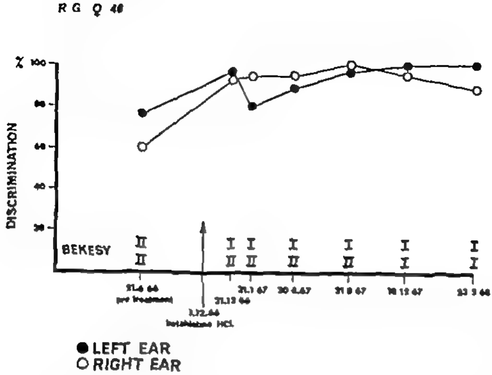

Fig 11 Evaluation of discrimination score and Békésy audiometry for patient whose tonal audiometry is shown in Fig 10.

various etiological causes and the absence of randomization The psychological and sociological aspects which can be added on to these characteristics of the study further complicate the project This last aspect is given great emphasis in our evaluation.

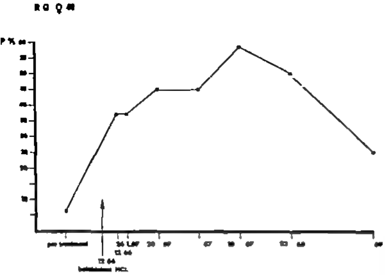
In this presentation we have shown our results in relation to modification of the subjective symptomatology and responses to tests of cochlear and vestibular functions. While the period devoted to this is yet too short since our longest treated patient has only been under treatment for 4 1/2 years, to have conclusive definite results, there seems to exist a definite pattern of response to both the vestibular and cochlear function tests.

The results of modification of the subjective symptomatology seems related to the severity of the disease being more effective in patients presenting what can be considered early stages of Ménière s syndrome whereas the effectiveness of the drug diminishes as the severity of the disease increases.

As far as the vestibular function is concerned there seems to exist a pattern of an initial increase of vestibular response to both caloric and rotational stimulation using the velocity of the slow phase as the parameter of analysis This initial increase has been noted in individual patients and a computerized summation of 40 patients out of the 102 included in this study in whom no other concomitant medication was given as far as could be ascertained by the author demonstrates this tendency to initial vestibular response increase (Fig 13) Wilmot (1972) has just presented his initial results in 11 patients in a three month study while using angular acceleration each patient had an increase of the vestibular speed of the slow phase

A longer time study however seems to demonstrate a secondary stage of vestibular response decrease We have no explanation yet to give for this secondary stage of vestibular response decrease However this is also present, but less marked for the audiological aspect

When the initial increase of vestibular response was first noted as in the patient described in Figs. 8 a b c who happened to be the third patient in our series, we stated in a letter to the pharmaceutical company (Bertrand, 1967) As I have stated to you since the very beginning when I have started using this



Summation of vestibular speed of slow phase at 30° and 44°C for right and left ears

Fig 12 a. Summation of vestibular speed of slow phase at 30° and 44°C for right and left ears.

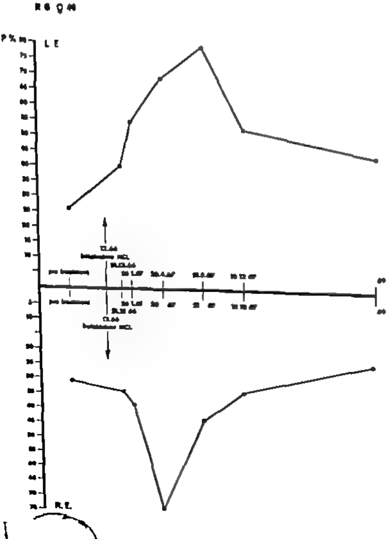


Fig 12 b Initial increase of vestibular response following rotational stimulation followed by secondary stage of response decrease (reproduced from *Laryngoscope* Vol. 85 p 894 June 1971).

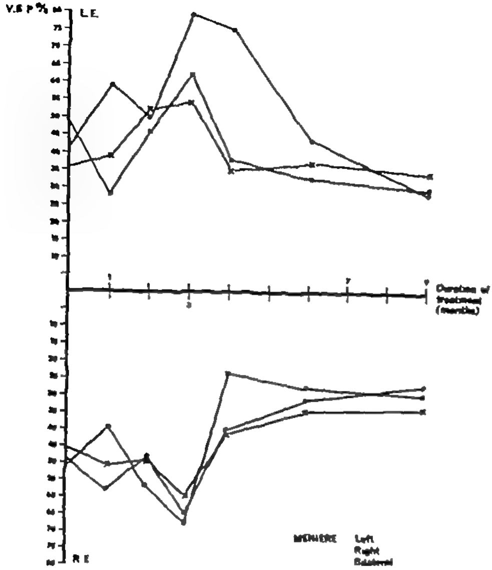

Fig 13 Average response of summation of VSP following rotational stimuli for pathological ear or ears during a 9 month period for 10 patients in whom *no other concomitant* medication or treatment were given (reproduced from *Laryngoscope* Vol 85 p 895 June 1971)

drug, I believe that the mode of action of betahistine HCl is not that of suppression or decrease of vestibular response as is the case in other drugs which I have studied, such as thiethylperazine, diphenidol or dimenhydrinate. In all of these drugs, a marked decrease of the vestibular response was noted in both the normal subjects studied according to the double-blind technique as well as in the pathological subjects." And further on "In Ménière's patients presenting as a rule an hyporeflective response we noted in many cases a clinical subjective improvement or disappearance of vertigo and at the same time, there seemed to be an increased response to the various vestibular stimulations"

Following these statements which were made in the initial stage of the use of betahistine HCl, two other researchers presented data concerning the use of betahistine HCl in animals.

Kubicek and his collaborators demonstrated an increase of the blood flow of the basilar arteries of dogs and hypothesized that this also resulted in an increase of the circulation in the labyrinthine artery

Martinez has just presented his findings that the use of betahistine HCl in a proportion of two tablets t.i.d. in a 75 kg man, increases the blood flow of the stria vascularis in the guinea pig within five minutes of intra-gastric administration and is accompanied by a tonic vasodilatation which lasts over an hour When betahistine HCl is administered intravenously

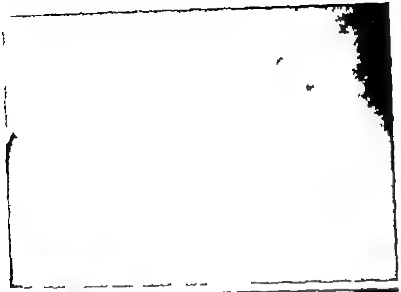

Fig 14 (*a*) Skin rash noted in a patient following administration of beta histine HCl, 24 mg daily for 1 month.

(*b*) Three weeks after drug withdrawal, the lesion was greatly diminished and had completely disappeared a few weeks later

Table III *Evolution of the symptom of vertigo in relation to severity of the disease*

Grade	No of pats	Controlled	Partially controlled	No improvement
I	11	10	1	0
II	49	28	19	2
III	42	5	15	22
	102	43 (42)	35 (34)	24 (23)

Martinez noticed an immediate marked vasodilatation, an increase of blood flow and capillaries not visible before administration of the drug were seen after such administration. This modification of the circulation of the stria vascularis as observed in the guinea pig can, due to the marked capillary vasodilatation probably lead to the modification of the permeability of these capillaries and thereby modify the endolymphatic pressure Personal communication of a preliminary study in this direction by Martinez seems to concur with this possibility

Suga & Snow (1969) recorded cochlear blood flow changes for various vasodilating drugs and some related agents, using a four electrode impedance plethysmograph. They demonstrated that betahistine HCl, at a posology of 0 01 to 0 4 mg per kg of body weight produced a cochlear blood flow increase in all 14 measurements on 13 guinea pigs The mean value and standard deviation were 224 ± 128 % of the control value, and the increase lasted more than 30 min

This modification of the circulation of the inner ear resulting in an increased blood flow as demonstrated by Martinez (1972) and Suga & Snow (1969) in the guinea pig, is assumed as also being present in man, capable of modifying the circulation in the stria vascularis, altering the capillary permeability and modifying the endolymphatic status. These modifications could then explain the results obtained in our longitudinal study thereby demonstrating that betahistine HCl is an effective drug.

CONCLUSIONS

1 Betahistine HCl seems effective in controlling the symptomatology of Ménière's syndrome or disease, especially in the early stages of the disease.
2. Many patients present transitory improvement of hearing in the early stage of treatment.
3 Objective vestibular function tests demonstrate an increase of the vestibular response in the initial stage of treatment followed by a secondary stage of vestibular response decrease.
4 With the exception of two patients having minor skin rash which disappeared following drug withdrawal, no major untoward complications were noted.
5 The effectiveness of this drug in certain cases of advanced Ménière's disease referred for surgical treatment has led us to a trial treatment period on all patients for whom we contemplated surgery

Table IV *Long-term evolution of symptomatology*

Symptom	No of pats presenting symptom	Completely controlled	Partially controlled	No improvement	Worse
Vertigo	102	40	38	4	0
Nausea	70	30	14	26	0
Vomiting	44	18	8	20	0
Tinnitus	102	20	32	96	4
Audition	98	8	20	68	2
Fullness	64	12	18	34	0
Headache	22	1	0	18	3

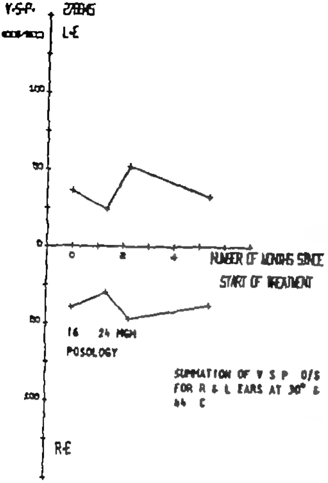

Fig 15 In certain cases in which there was no modification of the symptomatology or of the objective response, an increased dosage produced the pattern usually observed.

SUMMARY

Betahistine HCl was studied to evaluate its effect 1) in normal subjects and 2) in patients presenting Ménière s syndrome The subjective modification of the various symptoms of this syndrome as well as modification of audiometric and vestibular function were studied in 102 patients for periods of up to 4 1/2 years.

A double-blind evaluation of ten normal patients with betahistine HCl and a placebo did not show any statistically significant modification of the vestibular response

The subjective evaluation in 102 patients *seems to* indicate that the drug is more effective in the early stage of the disease Audiometric tests frequently demonstrated improvement of hearing in the early stages, but as a rule this improvement was of a transitory nature

Vestibular function tests, in patients who had no concomitant medication capable of modifying the vestibular response demonstrate a frequent increase of the vestibular response in the early stage of treatment followed by a secondary stage of vestibular response decrease.

No untoward complications were noted in a period of 4 1/2 years in 102 patients, except for a skin rash which disappeared when the medication was stopped

Following the work of Martinez (197?) and of Suga & Snow (1969) in the guinea pig, it is hypothesized that modification of the symptomatology in audiometric and vestibular response are due to modifications of the circulation at the level of the stria vascularis.

were not included into the study simply because there had been an exacerbation of their symptoms.

All patients were informed that they would receive a new and active drug, unknown to them they were given a placebo for the first 2 weeks of the study. After 2 weeks they were reassessed in the outpatient clinic after which they received betahistine. The first 5 patients started with 16 mg daily, later it was decided that a higher starting dose of 24 mg daily should be employed. If after 6–12 weeks at a particular dose the response was considered unsatisfactory the dose was increased, in one patient successive increases continued, to reach a daily dose of 64 mg. Throughout the trial no other drugs were given for Ménière's disease. But 1 patient with essential hypertension who had congestive cardiac failure received lasix and digitalis at intervals during the study.

At the first and each subsequent follow-up visit the patients were checked for nystagmus and Romberg's sign, the eye fundi were examined and the arterial blood pressure was measured in the sitting position after 10 min of rest. At intervals, throughout the trial pure tone audiograms were performed, these were not regularly spaced.

RESULTS

After starting the trial patient no. 1 (v. d. M.) who had shown no response to betahistine, was thought to have an acoustic neuroma. This diagnosis was confirmed and she was thereafter excluded from the study.

In this report will be presented only the results on the major symptoms, vertigo and tinnitus. The results of audiometric examination will also be discussed.

Patient's daily recordings

The information from these daily records involves more than 10 000 individual recordings. The results of all of these recordings can be illustrated graphically. The results of patient 1 (v. d. M.) who had an acoustic neuroma are not given. Some of the patients had already kept personal records of the severity of their symptoms before entering the trial, indeed one of

Proceedings of the Symposium on Ménière's Syndrome Zandvoort September 3 1970

A STUDY OF THE EFFICACY OF BETAHISTINE IN MENIERE'S SYNDROME

O R Hommes

From the Department of Neurology Radboud University Hospital Nijmegen The Netherlands

INTRODUCTION

Several reports have described the use of betahistine in the treatment of "Ménière's Syndrome"[1] This study was designed to assess the effect of the drug on the daily course of the disease during a period of at least 6 months. Such a detailed report on the long term daily symptoms of this condition has not to the best of our knowledge, already been reported in any study with any form of therapy for Ménière's Syndrome.

MATERIALS AND METHODS

The patients

Included in this study were 10 patients who had suffered for a minimum of 3 years from Ménière's Syndrome (Table I) By Ménière's Syndrome is meant a chronic progressive disease characterized by repeated troublesome attacks of vertigo and tinnitus associated with progressive hearing loss. There may have been additional symptoms of headache nausea and vomiting The diagnosis was independently agreed upon in the department of neurology and the department of otorhinolaryngology at the Sint Radboud Hospital (Table II) All patients had audiograms which were consistent with the diagnosis and caloric tests Most, but not all patients had other vestibular function tests (rotating chair) All patients were subjected to a thorough neurological examination including radiographs of the internal auditory meatus and lumbar puncture In 4 of the patients, 1 (v d. M), 4 (Co), 5 (v d. W) and 6 (Sp), internal carotid angiography was also performed All patients had been deemed *failures of medical treatment. The remaining* inclusion criteria for this study were that their symptoms had to be invalidating progressive and so frequent or persistent that they would produce a reasonably high score in daily reporting. It was in addition most important that all of the patients should be sufficiently intelligent and co-operative to maintain a daily written chart on the frequency and severity of each of their symptoms for at least the first 6 months of the trial.

These multiple references have an asterisk against them in the list of references.

METHOD OF ASSESSMENT

Before starting the trial it was explained to each patient how to keep a daily symptom score record They were also asked to record daily the severity in five degrees of the symptoms vertigo tinnitus, nausea and vomiting, deafness, ear pain and headache All of the patients had some persistent daily symptoms as an inclusion criterion for the trial, so the highest score was given for the occurrence of a symptom in sudden more severe exacerbations (Table III)

In addition, the physician kept a separate record of the patients symptoms as reported at each follow up interview Not until the physician was satisfied that a patient fully *understood the scoring system* was that patient permitted to enter the trial

TREATMENT SCHEME AND FOLLOW-UP

The time of entry into the trial was determined by the date of the routine attendance at the neurology outpatient clinic and not by the severity of the patients complaints. Patients

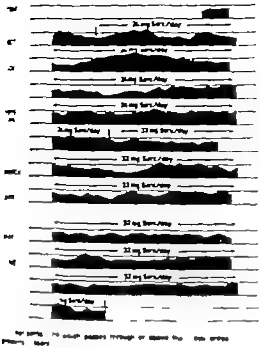

Fig. 1. Pat. 5 (d W.). A diagrammatic representation of the total daily symptom score throughout the study. Each daily score was taken from the patient calendars. The horizontal line which passes through or above the black areas represents score of 5.

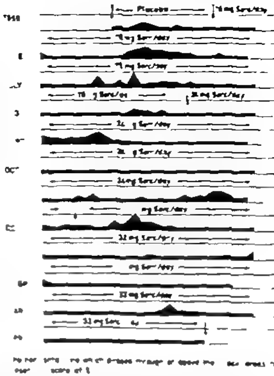

Fig. 2. Pat. 7 (Ha.). A diagrammatic representation of the total daily symptom score throughout the study. Each daily score was taken from the patient calendars. The horizontal line which passes through or above the black areas represents score of 5.

Vertigo, total scores for eight patients $p<0.05$

Tinnitus, total score of nine patients $p=0.05$

This analysis excludes the two weeks results because data were not available at this time from two patients because the physician was absent. In the statistical analysis the results of patient 4 (Co.), were included as being unchanged at 26 weeks, 40 weeks and the end of the trial.

Results of audiograms

Examination of the audiograms did not demonstrate that ny consistent improvement in hearing had occurred during the study nor was there clear indication that the progression of hearing los had been influenced. Preliminary evaluation of the results did suggest that the hearing improved in most patients during the first few months of betahistine treatment, especially at lower frequencies, but as no audiograms were performed on two subjects who had had unilateral labyrinthectomies and the audiograms were not regularly spaced, no attempt has been made to base any conclusions on these results. One patient (no. 5) showed an improvement in one ear of the order of 50 dB mean hearing loss at frequencies 500 and 1 000 Hz during the first months of treatment, after 6 months this improvement was still maintained. In the other ear there was an initial improvement of 20 dB at those two frequencies but 6 months later a further audiogram demonstrated that the hearing loss had returned to its original level.

Effects on social activity

them had kept daily records since 1965 and these records were also available for analysis. The total symptom scores were represented graphically Figs. 1–4 represent the total scores from 1 patient who was a failure of treatment (no 5) and 3 patients who responded (nos. 7 9 and 10)

All but two of the patients showed a marked decrease in the total symptom scores during the first 6–12 months after starting betahistine. Closer examination indicates that in the successful patients was a fall in the baseline the height of the symptom peaks was reduced and a decreased incidence of symptom peaks running together indicates a reduction in the duration of the episodes of increased symptoms.

Physician's assessment

The results from the physician's assessment demonstrated a trend which was similar to that seen from the patient's own record keeping During the first 6 weeks of treatment although some patients improved the results were not dramatic between the 10th and 20th week of treatment improvement in the symptoms vertigo and tinnitus became much more clear This improvement continued to increase during the subsequent 20 weeks and when the patients were re-assessed before making this report, this improvement could be seen to be maintained.

Two patients did not respond to betahistine one of these (no 4) (Co) had very severe persistent symptoms, and although there was a marked decrease in the symptoms nausea and vomiting in the view of the absence of change in tinnitus and vertigo the treatment with betahistine was stopped after 29 weeks the other patient (no 5) (v. d. W) had shown no consistent improvement after 44 weeks of treatment.

Tables IV and V show the change in the number of patients showing a consistent improvement on betahistine as the trial progressed The date of the final assessment was between 44 and 86 weeks after entering into the trial.

From these tables it can be seen that in 6 patients there was a consistent improvement in vertigo one was unchanged and one was worse at the time of making this report Six patients demonstrated consistent improvement in tinnitus and 2 were unchanged. For both symptoms the change in number of patients who improved is statistically significant

Table VI illustrates the total symptom scores for vertigo and tinnitus at intervals throughout the trial This type of scoring system belittles the extent of any change which is seen, for example a change of only one figure in the individual score for tinnitus could mean the difference between a patient being incapacitated at home or actively working This is better understood when it is considered that an improvement in a particular symptom was usually paralleled by an improvement in one or more of the other symptoms.

The trends in total score values were tested for statistical significance using Spearman's test of rank correlation

treatment on their ability to work. The total symptom charts of patients no. 5 (failure) 9 and 10 illustrate the daily symptoms in 2 of the patients who respond compared with 2 patients who did not respond to treatment. The change in disturbance of daily life can be clearly seen in patients 9 and 10.

Dose of betahistine

The maximum dose of betahistine employed at the time of making this report is 64 mg daily, the minimum dose for any patient at this time is 24 mg daily.

Side-effects

One patient (no. 6) (Spi.) had an exacerbation of bronchial asthma which lasted for 2 weeks when he first received the active tablets. This patient had had asthma before it become apparent that he had Ménière's Syndrome; this was the first attack that he had had since the latter diagnosis was made 8 years previously. After 2 weeks of betahistine treatment the exacerbation subsided and no further episodes occurred during the subsequent 56 weeks of treatment. Three other patients had a past history of allergic disorders, but none of them

Final assessment 44–86	6	0 (1)	1 ($p = 0.06$)

experienced a return of his or her earlier condition

No other adverse effects of the medication were noted

Results of other observations

No marked changes were seen in blood pressure in any of the patients during the study There was noted in most of the patients an increase in the pinkness of the retinal macula during the first few weeks of therapy but this is a subjective finding that is so difficult to quantitate that confirmation would need to be carried out in a more objective manner

DISCUSSION

A difficulty which arises in studies of the effect of a particular type of therapy in a condition like Ménière s Syndrome" lies in the selection of the method of control. These results show a clear improvement in the symptoms vertigo and tinnitus and also in the total symptom score for most of the patients during the trial

Such an effect might be falsely attributed to the therapy under test under the following circumstances

1) If at the time of inclusion into the trial the patients were in the midst of an unusually severe exacerbation or deterioration.

2) If the method of assessment or recording were changed during the course of the trial.

3) If the patient s judgement of the severity of his symptoms was altered during the course of the trial

4) If the treatment of follow up involved in the trial were associated with a marked and increasing placebo" effect.

5) If almost all of the patients happened to be selected at a time when their disease process was "dying out"

Each of these possibilities has been considered. The date on which each patient was included in the study was determined by the date of his or her routine clinic attendance and the time of the year that the trial began was determined by the availability of the betahistine tablets All patients entered the trial between May and October 1968

Throughout the trial the method of recording the results remained unchanged but some patients did not continue to keep daily records after 6 months. If this had influenced the physician s assessment of the symptoms obtained from questioning the patient then there might be expected to be a trend of change in the physician s record, which corresponded with the cessation of the maintenance of personal records by the patient. Such a trend was not seen

It could be suggested that participation in this trial and attention from a physician could

lead to either a decrease in the patients' own assessments of the severity of their symptoms or that the improvement seen was a prolonged placebo effect. It can be seen from the patient's total symptom charts however that throughout the study there occurred not only a progressive decrease in the severity of the symptoms, but also in the incidence of exacerbations. A placebo effect is most marked during the first few weeks of treatment when the patient is hopeful and perhaps enthusiastic about receiving a new or different form of treatment. In a disease such as this, which in these patients had shown itself to be incapacitating and progressive, an increasing placebo response would be remarkable.

The final possibility which must be considered is that at the time of entering the trial, in most of the patients the disease process happened to be at the stage of 'dying out' that is the stage of the disease, where the severity and incidence of the episodes of vertigo, nausea and vomiting diminish and where the loss of hearing remains constant or increases gradually. The outcome of the condition is not reliably predictable, its duration is variable and the degree of damage which has occurred if or when progression apparently ceases is impossible to forecast, it is therefore not possible to make a judgement on the stage or future course in these patients on the basis of duration or severity of symptoms at the time of beginning the trial. However 2 patients had kept records before the trial started, these did not suggest a progressive improvement in symptoms before treatment. It would be an unusual coincidence if the very patients selected for this study were not only in the phase of the disease where symptoms were decreasing, but were selected for inclusion at exactly that time when a noticeable decrease in the frequency of attacks and severity of their symptoms was about to occur. They were, in fact, included only because they were becoming progressively more incapacitated, and demonstrated no response to any of the treatments which were tried.

(Spearman's test of rank correlation)

It has been postulated that as a dilator of the microcirculation betahistine acts by improving the blood supply to an ischaemic inner ear (Elia, 1965 *b*; Godlowski, 1965).

Animal studies have demonstrated that stimulation of the sympathetic nerve supply to the inner ear gives rise to vasoconstriction and a reduction in the size of the cochlear microphonic potentials (Seymour & Tappin, 1951; Seymour 1953, 1954).

Topical application of adrenaline to the stria vascularis of the guinea pig has demonstrated that intense spasm may occur which may last for several hours (Hunt & Fossbinder, 1947). In patients suffering an exacerbation of the symptoms of Ménière's disease, cervical sympathetic block may give rise to an immediate improvement in vertigo and a diminution in low tone hearing loss (Walter, Hunt & Fossbinder, 1941; Wilmot, 1957, 1960, 1961). In addition the reported beneficial effects of cervical sympathectomy and case reports on the benefits of vasodilators and histamine infusion (Wilmot, 1957, 1960, 1961, 1969) are in support of the concept that Ménière's Syndrome may be due to impaired blood flow to the inner ear. If this could be assumed to be proved then the activity of Serc could be attributed to its

microcirculation dilatory effect (Walter et al 1941 Hunt & Fossbinder 1942 Baez, 1968 1969 Suga & Snow 1968 1969)

SUMMARY AND CONCLUSIONS

Nine patients suffering from Ménière s Syndrome were treated with betahistine hydrochloride tablets for from 29 to 84 weeks continuously Daily symptom records were kept for at least 6 months in all patients and for longer in the majority At each outpatient visit the physician made a separate assessment of the patient s condition Audiograms performed before and during treatment were compared

The results showed that during the course of the study there was a progressive improvement in the symptom scores for vertigo and tinnitus. The trend of improvement was statistically significant. No clear adverse or beneficial effect on hearing could be seen from the audiograms Successful treatment with betahistine was accompanied by a marked improvement in the patients social activities

One patient who had previously suffered from asthma, had an exacerbation during the first 2 weeks of treatment with betahistine No other side-effects were reported.

The possible causes for the beneficial effects and the proposed mechanism of action of betahistine are briefly discussed

It is concluded that this progressive improvement in the symptoms tinnitus and vertigo in Ménière s disease is attributable to the treatment with betahistine.

HOW SHOULD A TREATMENT OF MÉNIÈRE'S SYNDROME BE EVALUATED?

Panel Discussion

Panel Chairman and Editor· R. R. A. Coles

University of Southampton Southampton England

Chairman We have had many papers and much useful discussion today which have highlighted in different ways most of the problems concerned in any kind of therapeutic trial in Ménière's disease The biggest problem is the question of natural exacerbations and remissions, and the long period of follow up which is needed. This is five years according to McNally's recommendations, but we now have a suggestion that for a perfect trial, a much longer followup still is needed. This is one of many considerations on which we are forced into practical compromise as distinct from the ideal

One difficulty is in deciding what you regard as a cure and if you are going to talk about cures, a thing which has not yet been discussed in this symposium is whether the cases should be subdivided into early ones and long standing ones. In early cases it is relevant to consider the possible effects on hearing and tinnitus, also perhaps certain changes in sensitivity to caloric testing whereas in long-standing cases probably the hearing is already fairly bad and irreversibly so then, you cannot expect a return to anything like normal hearing but you may still achieve a cure" because by this time the major complaint is vertigo which presumably arises from fluctuations in the resting tone of the affected vestibular organ and nerve Then there are the ethical problems associated with double-blind trials placebos, cross-over trials.

Finally or rather firstly there is the question of what criteria you are going to use to define the disease entity on which you are going to try to run a therapeutic trial. I think therefore that our panel discussion should commence with a discussion of the diagnostic features of Ménière's disease and Ménière's syndrome Should one include a wide variety of cases, or should the diagnostic criteria be strictly defined, or should the trial cover both diagnostic groups? Some have advocated fairly tight diagnostic schedules for Ménière's disease patients, together with a second more heterogeneous group termed Ménière-like syndrome or pseudo-Ménière's disease or some such name May I have some views on this, please?

Hinchcliffe Relevant to the Chairman's questions, there is the problem of whether or not such conditions as Lermoyez syndrome pseudo-Ménière's disorder and vestibular neuronitis are "formes frustes" or atypical forms of Ménière's disorder or whether they represent nosologically distinct disorders. There are now quantitative techniques, e.g. numerical taxonomy available which can indicate whether we are dealing with a homogeneous population or a heterogeneous one Our own application of these methods has shown that after we have excluded such acceptably distinct disorders as those due to toxins, trauma or organic disease of the nervous system, there re

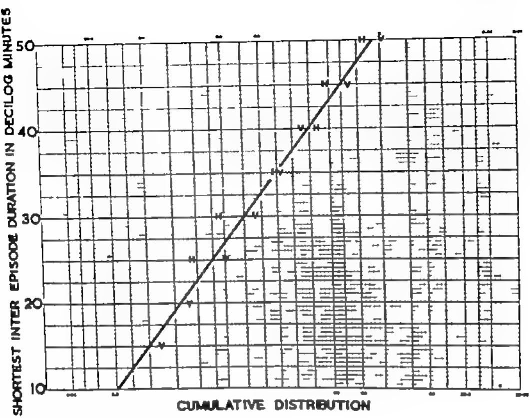

Fig 1 (Hinchcliff) *Cumulative distribution of shortest inter-episode durations in Ménière disorder* (*V* vertigo, *H* headache)

mains a homogeneous population of vertiginous disorders In short, all other Ménière form disorders are most likely to represent Ménière s disorder in one form or another Thus, in the hypothetical study that we are considering today not only is it not necessary to exclude Ménière-form disorders other than the typical condition, but, since in overall medical practice they may be commoner than those showing the classical characteristics, it should be mandatory to include them.

In contrast to the concept of the homogeneity of Ménière s disorder—as a clinical condition—is the concept of a multifactorial aetiology Such a concept would help to reconcile, for example, the apparently conflicting assertions that the disorder is, on the one hand, an allergic one, and, on the other hand, a psychosomatic one. With respect to asthma, Kourilsky has reported that crises are always preceded by anxiety and that suppression of the emotional stimulus results in suppression also of the allergic manifestations.

Finally might I show some slides that demonstrate the distribution of some basic quantitative measures in the symptomatology of Ménière s disorder These measures could conceivably be of value in the assessment of therapeutic trials and in the comparison of the different series of cases reported by various authors so that we might ascertain how comparable these various samples are. Slide 1 shows the distribution of the shortest inter episode duration with respect not only to the

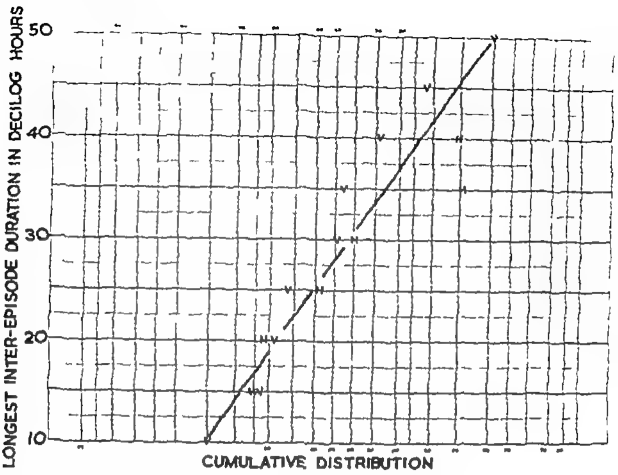

Fig. 2 (Hinchcliffe) *Cumulative distribution of longest inter-episode durations in Ménière's disorder* (*V* = vertigo *H* = headache).

vertigo which affects patients with Ménière's disorder but also the headaches from which many of them also suffer The duration is expressed on a logarithmic scale It will be noted that not only do the shortest inter-episode durations of vertigo exhibit a straight line plot i.e. a Gaussian distribution, but those with the headaches do also Moreover it is the same Gaussian distribution Slide 2 shows similar results for the longest inter-episode duration for both the vertigo and the headaches. The data indicate that in 2% of Ménière's patients, the longest inter-episode duration is more than ten years. Thus it can be argued that failure of a patient to have any more attacks in their lifetime is merely because the inter-episode duration has been extended to a period beyond their life span

Slides 3 & 4 show that there is a trading relationship between severity of the physiological deficit in Ménière's disorder and the personality aberration in these patients.

Chairman Any other contributors on this before I attempt to summarize upon that? No? Well we seem to be in complete agreement that one has to exclude other conditions very rigorously But what do we do with the remainder? One approach is to put them into two groups. (i) Those with the classic triad of symptoms, supported by appropriate signs yielded by the threshold audiometric, differential diagnostic, and vestibulometric tests that have been discussed in various papers. (ii) A second group in which the symptomatology is not quite classical such as cases which have not

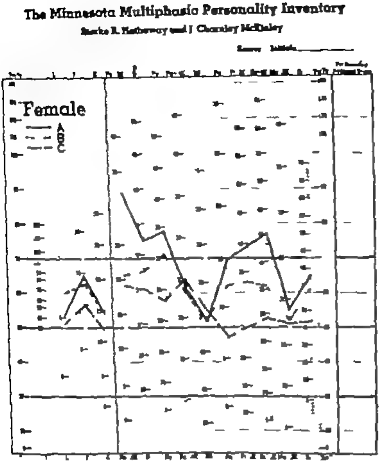

Fig. 3 (Hinchcliffe). *Relationships between hearing level and personality aberration in Ménière disorder. Group I (USA)* (*A* = median scores for subgroup with hearing level <30 dB (ASA 1951) at 500 Hz, *B* = HL 30–60 dB, *C* = HL >60 dB).

had tinnitus, or they have not had much deafness. One rather hesitates though to put in cases of deafness and tinnitus without vertigo. I think, Dr Hinchcliffe, that you would agree that episodic vertigo is the one symptom you cannot exclude although you may do without tinnitus or without deafness. Having classified the cases in two separate groups, you can either use both groups or if you wish to restrict the size of the trial and obtain maximum precision, you can simply stick to as many classical cases of Ménière's syndrome as you can find.

The other approach, put forward by Dr Hinchcliffe, is simply to lump the material together and, if I understand him correctly, to do an analysis of the homogeneity of the group as a whole. I am not entirely clear how you

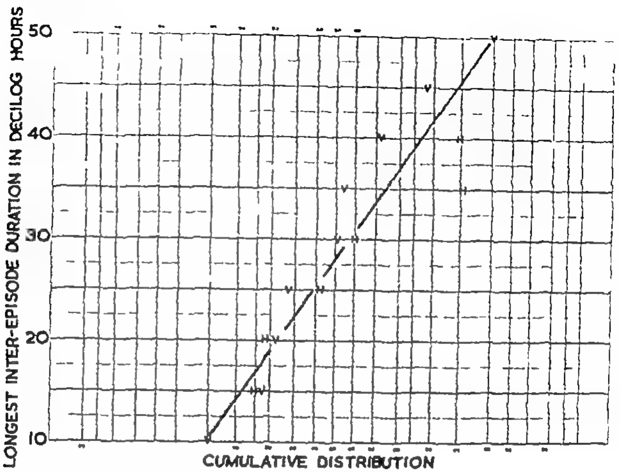

Fig. 2 (Hinchcliffe) Cumulative distribution of longest inter-episode durations in Ménière's disorder (*V* = vertigo, *H* = headache)

vertigo which affects patients with Ménière's disorder but also the headaches from which many of them also suffer The duration is expressed on a logarithmic scale It will be noted that not only do the shortest inter-episode durations of vertigo exhibit a straight line plot i.e a Gaussian distribution but those with the headaches do also Moreover it is the same Gaussian distribution Slide 2 shows similar results for the longest inter-episode duration for both the vertigo and the headaches. had tinnitus, or they have not had much deafness. One rather hesitates though to put in cases of deafness and tinnitus without vertigo. I think, Dr Hinchcliffe, that you would agree that episodic vertigo is the one symptom you cannot exclude although you may do without tinnitus or without deafness. Having classified the cases in two separate groups, you can either use both ... if you wish to restrict the size of the trial and obtain maximum precision, you can simply stick to as many classical cases of Ménière's syndrome as you can find.

The other approach, put forward by Dr Hinchcliffe is simply to lump the material together and, if I understand him correctly to do an analysis of the homogeneity of the group as a whole. I am not entirely clear how you

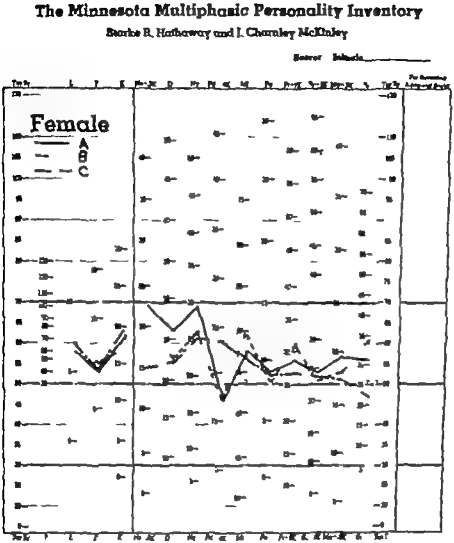

Fig. 4 (Hinchcliffe) *Relationships between hearing level and personality aberration in Ménière's disord Group 2 (U.K.) (A – median scores for subgroup with* hearing level in poorer ear <50 dB (BSI 1954) at 500 Hz, *B* – HL 50–60 dB *C* – HL >60 dB)

proceed with that, but I'm afraid we cannot go into it in any more detail now

(Question) Could I ask Dr Hinchcliffe a question? There is a condition which has been recognized by Hallberg consisting of cochlear hydrops only: that is, hydrops of the cochlea without any hydrops of the utricle and saccule. And it is believed that many of these patients develop vertigo later. In this specification when does the non-classical enter the classical phase?

Hinchcliffe I agree that difficulties always arise when one uses what medical people usually use i.e. a monothetic system of classifica

tion. According to this system a patient may be wrongly classified because of a failure to exhibit a crucial characteristic. For the purposes of our study I would agree that we must exclude any patient who does not suffer from vertigo. The clinical concept of Ménière's disorder is not identical with the histopathological concept of endolymphatic hydrops (Berggren, 1949; Wustrow & Borkowsky, 1960).

Chairman. Thank you. I do not think we have any particular difficulty there between the ideal and the practical compromise. It is a question of individual requirements and availability of facilities and time.

Wilmot. It seems to me that the biggest problem in differential diagnosis is not acoustic neuromas or head trauma or vestibular neuronitis, but the other vascular conditions which affect the head and neck, particularly the atherosclerotic group of patients. These are the people who present with vertigo, not necessarily of the classical Ménière-type, but who get giddy attacks; they often have bilateral hearing losses, which are not always equal. Sometimes, indeed quite commonly, they show evidence of recruitment and they often have good speech discrimination. Yet these people have not got Ménière's disease, although they may well have some endolymphatic hydrops as the result of a generalized disease process.

Now what we have been trying to do today, I think, is to sort out the effects of betahistine on the micro-circulation of the inner ear. But the greatest confusion in treatment is going to arise between people with a genuine micro-circulatory problem, which is probably psychosomatically induced, and a very much larger group of patients who are more often in older age groups and have pretty clear evidence of atherosclerosis which may be affecting the coronary arteries, the leg arteries, or the vertebrobasilar system. This is the group that really has got to be sorted out, and this is the group that we should know as much about as possible. I believe that the classical Ménière's syndrome has a different vestibular reaction than this group. Also the cases of head trauma and of vestibular neuronitis and so on.

The first thing we have got to do is to concentrate on the sort of testing which Dr Bertrand has been doing on a large scale and I have been doing on a smaller scale. This is in actually trying to measure vestibular function, because too much reliance upon audiometry and upon the caloric test have not really supplied the answer. What we have got to do is to see what difference in vestibular reactions we get in these different groups.

When you get a group of patients coming with vertigo, you have got to, as Professor Jongkees said this morning, examine the cervical spine and the cervical muscles. You have got to look for interstitial keratitis and you have got to do a thorough medical examination. You must spend time on these patients. But, *primarily*, you have got to exclude the effects of generalized atherosclerotic processes upon the inner ear.

Chairman. Thank you very much. I entirely agree. We have recently at Southampton been following up some of the work done by Litton & McCabe (1967) in the United States with their technique of "thermal vestibulometry". I know Dr Hinchcliffe, in London, has been doing likewise and I expect quite a number of other persons have too. In this, you do a series of cold caloric tests, gradually giving more and more cold stimuli until limited by the patient's discomfort. According to their paper and supported by our own results and, I think, those of Dr Hinchcliffe too, this test seems to give a good differentiation between the *central* type of vestibular disorder and the peripheral one. Now I am not suggesting that this is the only technique for doing this. Mr Wilmot is recommending rotational vestibulometry. What I am quite sure of is that there is a lot more to be done in developing means of differential

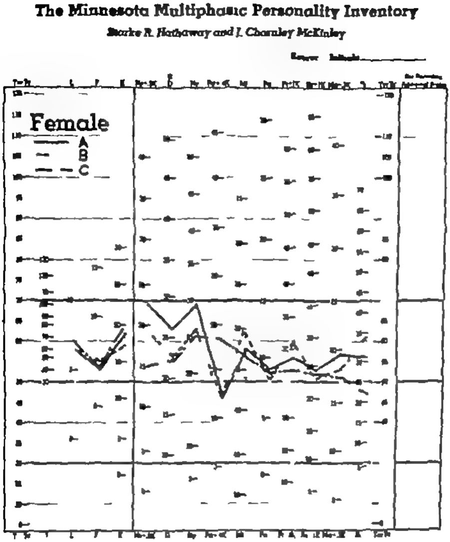

Fig 4 (Hinchcliffe). *Relationships between hearing level and personality aberration in Ménière's disorder Group* (U K) (*A* – median scores for subgroup with hearing level in poorer ear < 50 dB (BSI 1954) at 500 Hz, *B* – HL 50–60 dB *C* – HL > 60 dB)

proceed with that, but I'm afraid we cannot go into it in any more detail now

(*Question*) Could I ask Dr Hinchcliffe a question? There is a condition which has been recognised by Hallberg consisting of cochlear hydrops only that is, hydrops of the cochlea without any hydrops of the utricle and saccule And it is believed that many of these patients develop vertigo later In this specification, when does the non-classical enter the classical phase?

Hinchcliffe I agree that difficulties always arise when one uses what medical people usually use, i.e a monothetic system of classifica

ideal is surely to do every test that has been mentioned, but again we need a practical compromise. I think it would help therefore if we try to define what we regard as the minimum investigation. Would Mr Wilmot like to suggest what he would regard as the minimum investigation and then we can argue about what more must be added?

Wilmot It does seem to me that this is the crux of the whole thing. One must do pure tone threshold tests, by air and bone-conduction The simplest method of showing recruitment, in one or both ears, is to do a loudness discomfort level test, so that this could be your only test for pure-tone recruitment. The SISI test is not essential. Békésy audiometry is also essential to measure tone decay unless you are doing a special tone decay test. To recapitulate: air-conduction, bone-conduction, loudness discomfort level, *Békésy fixed-frequency* at 250, 1 000 and 4 000 Hertz, and a speech discrimination score. These are the essentials, provided you are quite certain that the deafness is purely neuro-sensory and that there is no conductive element If there is any doubt about this, then the acoustic impedance meter is also required

Hennebert I am afraid all the tests that Mr Wilmot describes are too time consuming I do not think that the bone-conduction tests must be done in every case with a tuning fork we can very well form an opinion about transmission Concerning tone decay my experience is that only 4 000 Hz is sufficient to demonstrate it It is far less frequent in the other frequencies

Chairman The minimum audiological requirement for patients who are going to take part in a therapeutic trial on Ménière's syndrome depends on the degree to which you are aiming to refine the diagnosis Personally I would like to see the sort of audiological work-up which has been described, but we can agree to differ in detail.

Hinchcliffe Could I de-emphasize audiological and vestibular measurements? One of the most valuable sources of diagnostic information, when we wish to ensure whether or not we are dealing with Ménière's disorder (especially vis-à-vis intermittent vertebro-basilar artery insufficiency), is the questionnaire, or anamnesis or history or whatever we wish to call it.

In the physical examination, a neurological examination covering at least the cranial nerves is necessary An examination for interstitial keratitis is mandatory in the ophthalmological examination

Frew I would also suggest that some radiological investigations, not necessarily of a complicated kind, should be added. At least, an X-ray of skull and an X-ray of the cervical spine. I noticed in Dr Hommes' paper that he did in some investigations a probably unnecessary lumbar puncture, together with radiology of the internal auditory meatuses and an internal carotid arteriograph. Surely the vertebral artery plays a bigger part than the internal carotid here. Basic radiology of the internal auditory meatuses is all that is needed unless one is going to do a full tomography and may be go on to contrast studies, which are not indicated at this stage. And as you know House and his co-workers found that something like 40% of acoustic neuromas when they are small have normal lumbar puncture protein.

Chairman. I think I want to get a consensus of opinion on whether radiological investigation should be an essential part. We'll consider it generally: it might be X-ray of the internal auditory meatuses, it might be X-ray of the cervical spine, it might be arteriography or it might be all of these. Those who feel that radiological investigation is essential to the proper screening and investigation of patients to take part in a therapeutic trial in Ménière's syndrome, please show their hands? Fourteen. And those who feel it should not be? Two.

Lumbar puncture? Personally I would feel

diagnosis of vertigo using either or both thermal and rotational vestibulometric techniques

Bertrand I would like to comment briefly on the possibility of vestibular "recruitment" from rotational stimulation Vestibular "recruitment" has been defined by Litton & McCabe (1967) as "a response that is diminished near threshold building to greater increments of response as *one proceeds higher above threshold* by equal stimulus increments" They concluded that no vestibular recruitment" was observed in hair-cell lesions. It is to be noted however that the vestibular stimuli used consisted of *graduated caloric irrigations. Mr Wilmot's re*commendations of rotational vestibulometry certainly warrant further investigations. We have used routinely rotational stimulation with angular accelerations of 1 3 and 6 $/s^2$ and a sudden stop from 90 /s constant speed. In the normal ear the response using the speed of the slow phase as the parameter of analysis, is proportional to the stimulus used. Occasionally though, in the pathological ear from a marked hyporeflective response at the lower stimulations (1 and 3 $/s^2$ and even 6 $/s^2$) with the stronger stimulations of 6 $/s^2$ and a sudden stop from 90% the response frequently equalled that of the normal ear So that there seems to be a catching up" of the intensity of response obtained for the hyporeflective pathological ear with lower stimuli to that of the normal ear when stronger stimuli are used This could possibly be construed as "vestibular recruitment This phenomenon of "vestibular recruitment has been described by Greiner Conraux & Collard (1969) These authors claim that following torsion swing stimulations it is present in 5% of 2 000 analysed ENG recordings can be of a transitory nature and in 19% of the cases, when it is present, is related to a peripheral vestibular pathology This is compatible with our results.

Chairman I would like to ask you quite simply how do you stimulate the left ear only with the rotation test?

Bertrand It certainly must be agreed that rotational stimulation can and does, stimulate both ears. Nevertheless, physiological data seem to indicate that, for the horizontal semicircular canals, *an ampullopetal stimulation* evokes a stronger response than an ampullofugal stimulation An anticlockwise rotation would then elicit a response predominantly from the left labyrinth and vice versa for a *clockwise rotation*

Chairman I am afraid I would not agree but as Chairman I am *going to rule myself out of* order to argue it further

Wilmot Mr Chairman could we refer to left function and right function in terms of rotation test not left ear or right ear

Chairman Yes

Wilmot Can I just say something about recruitment in vestibular function because I would like to believe what Dr Bertrand said—that one gets recruitment in vestibular function the same as one does with auditory function in many cases of Ménière's syndrome—but this is not my experience In fact, I believe that one has the opposite finding in many cases of Ménière's syndrome. I find a remarkable lack of change of reaction in comparison to change in stimulus, and when you do exceed threshold, the reaction is much less than you would expect. So at the moment I am not in agreement with Dr Bertrand on this aspect of vestibular recruitment

Bertrand I am not saying at the present time that this catching up of vestibular response noted in certain cases is "vestibular recruitment" but only that this example may possibly be "vestibular recruitment"

Chairman I think we should now move on to the question of the pre treatment investigation From various papers, you have heard a whole host of tests that you could do The

that most people would feel that this is essential I cannot conceive of it being left out. Would you agree? I am not suggesting that is the only vestibular function test. Does that dispose of the comments? Yes.

What additional tests? I would say positional nystagmus tests would have to be done and presumably investigation of any spontaneous nystagmus with electronystagmography (or electrooculography) and see what the effects of removal of visual fixation are. If they are abolished or reduced by darkness or eye closure, then it is probably a central disorder and not a peripheral one. This would seem to me an important differential diagnostic point. I suppose optokinetic nystagmus tests should also be performed, although I have always had difficulty in interpreting them. Is the general feeling that one should have the full vestibular investigation that is, positional, spontaneous, optokinetic and caloric tests? Yes

Now we come to the rotation tests Some feel that they have a great deal to offer On the other hand there is one practical problem. a lot of people have not got the expensive and bulky equipment needed Personally I feel that these tests should be optional only but this may be because I am biased by not being familiar with the technique and not having the equipment myself Would someone like to present a case for rotation tests being essential to this investigation?

Wilmot I think the crux of the question is getting the stimulus at the right level. The caloric test is a crude test. However you carry it out, it is still crude, and we should be concerned with very minor changes in vestibular function All our emphasis in Ménière's disease for many years has been wrong. Our emphasis has been on the established disease after the reversible stage has been passed It is only by changing our emphasis into interest in the early manifestations of vestibular disorders that we can ever really do anything to help our patients. The only time that this disease is really reversible is early We must have equipment that shows us early changes of function. Not equipment comparable to dropping a brick on a man's toes and asking: Does that hurt?" He should be able to feel a feather and it is exactly the same in balance testing in that you need a development of the caloric test that gives the same fine degree of sensitivity which the rotation test gives. When this is possible I will take much more interest in the caloric test. I would say that anybody who is going to make any real progress in treating his patients has got to develop a method of fine vestibular stimulation.

Chairman. You would regard this as an essential feature for a trial of a drug or of any treatment? The terms of reference to this panel is how should a treatment of Ménière's syndrome be evaluated? Do you feel that this rotation test is an essential feature of the preliminary investigation?

Wilmot Can I put it that anybody who can deliver fine vestibular stimuli with any equipment and can show repeatable results, then he should be allowed to investigate this condition. If he has not got equipment that will show this type of alteration, then I do not think he is in a position to evaluate a drug or a method of treatment.

Chairman. I am tempted, unless people disagree, to suggest that this should be an optional extra. If you have the facility to do it, use it by all means it will add to the value of the trial, but it is not an essential. Is there any disagreement on that? No.

Hennebert I would just like to draw attention to another method of rotation evaluation. This is the alternate method, which we have used in the last few years and which is used in many centres in France and in Belgium It is very easy It is cheap, it is quite well normalized and standardized, and it is possible to reproduce the test results very well.

that this was not part of a routine investigation *It has quite a bit of morbidity attached to it* in some hands at any rate, and it is unpleasant for the patient. Would those who feel that lumbar puncture should be a standard part of such an investigation please show their hands? None Those who feel that it should not? Most think not. I am glad that you agree with me Perhaps we can put it down as an optional extra. Let us now take the personality inventory which has been suggested by Dr Hinchcliffe Would Dr Hinchcliffe like first to define what he means by this

Hinchcliffe First should the patient be examined by a psychiatrist and secondly should one use some quantitative measure of personality? That great English physician Ryle said "Measure the measurable and attempt to measure the immeasurable There are lots of criticisms levelled at the MMPI (Minnesota Multiphasic Personality Inventory) but this measure is not only a quantitative one but correlations have been established between scores on its scales and various measures of auditory (see slides 3 & 4) and vestibular deficit in Ménière's disorder

Chairman I want another show of hands *please By those who feel that a personality* inventory is an essential part of the preliminary investigation? Three By those who feel it should be an optional part which you can use *if you are so inclined? Nearly everyone*

Are there any other essential investigations required?

Martinez I am not sure whether emphasis has been given during the neurological examination to examination of the gait with eyes closed and also the examination of the fundi of the eye by the otolaryngologist who is seeing the patient that is, not necessarily requesting an ophthalmological consultation in all patients.

Wilmot Could we *modify Dr Martinez* suggestion to clinical tests of balance?

Chairman Yes, you are saying that a good practice of otology should be able to encompass balance tests without having to bring in a neurological specialist, and ophthalmic examination without routine need for reference to an ophthalmologist.

Wilmot One does get a lot of information from simple tests, like standing on one leg, heel-toe walking tiptoeing quickly defence of equilibrium, and so on and the whole of these tests can be run through in about one or one-and-a-half minutes. Another question though, is how are we going to exclude manifestations of atherosclerosis? These often appear later although with hindsight one might have suspected them at the first consultation.

Stuart I would suggest listening to the arteries in the lower part of the neck You can often hear bruits. This is just one point there are of course many points in the history also The other thing I like to make a plea for is the 30-degree caloric test. If you do not get a response to a 30 degree caloric test, I think the patient should be investigated for an acoustic neuroma, especially the patient who is deaf If you do not do this, you will miss the odd acoustic neuroma.

Chairman We should certainly include listening to the neck vessels as a particular test, but obviously general cardiovascular investigation not least at any rate measurement of blood pressure and pulse rate, and rhythm, is needed. We shall come to calorics in a moment.

Martinez Still on the *question of* atherosclerosis, the fundus is *very important* and I would also rotate the neck and look for nystagmus which may arise if the arterial supply becomes *shut off by the torsion of the neck.* I would call cases like these vertebrobasilar insufficiency rather than Ménière's syndrome.

Chairman On vestibular function we have already mentioned caloric tests. I would imagine

You can still do your analysis of the whole group, but later if you have them sub-divided in this way you can, as you go along, collect more and more and eventually analyse each sub-division separately I would go along with Dr Bertrand on this and say that we should have a definite method of grading along exactly the lines that he said.

Flynn. I also would agree with Dr Bertrand and Dr Wilmot but I would go a stage further especially if very small numbers are involved in a controlled trial, because if you have random allocation to one of two or more treatments, with small numbers you have a very good chance that you may not have comparable groups. You may run into trouble despite the fact that everything was double-blind. For instance, if you have ten patients in one group and ten patients in the other group in the first group you might have eight who are in the early and reversible stage of the disease and in the second group eight who are in a late stage of the disease. This is something that you cannot predict and something you cannot avoid, unless you select and categorize the patients before you allocate them to a form of treatment.

Chairman. And you have a different statistical plan for each of these sub-groups? You allocate them to a sub-group and then according to the sub-group you would give each patient either placebo or drug according to some prearranged plan?

Flynn. Yes.

Chairman. That seems to be a very sensible precaution

Hinchcliffe I would not agree that one should restrict the number of grades in one's assessment of severity to three. It would be better to use more grades of severity It has been shown that, even if one wants to come out with three grades eventually more precision can be achieved by asking the observer to use a 9-point scale than collapsing results to give a 3-point scale

Chairman. In any kind of experiment one ends up by adding, adding, adding to it. I recall how I used to battle with our statistician in deciding what number of subjects to plan for She always seemed to double the number I thought of as enough, but I knew she was going to do that so I quartered the number I thought she would ask for and so on. Thus, experimental decision is so often a question of practical compromise.

Coming back now to our topic, I think the ideal is to have three groups, and a separate statistical plan for each of these groups. But is there any practical compromise that could be suggested here for smaller trials? Well, I think the answer is simply to take your patients, classify them, and present results for each class or grade separately But unless you are going for a relatively large study I do not think you could follow your point, Dr Flynn, very easily because you would then need a minimum of say 30 patients or something of that sort. You would do that if you can, but only if your study is big enough.

We come now to the question of controls. This either involves placebo treatment, or the history of that *particular* patient before he was included in the *trial* and came under treatment, or simply a comparison with the known if it be known, natural course of Ménière's disease aiming to show that the expected progress would be such and such and your treatment has modified it and made it something *different.* The first question then is whether you can compare treated results with the known history of Ménière's disease and use that as the control? My own feeling is that the course of Ménière's disease is too variable for this.

Hinchcliffe No, Mr Chairman you may remember that I have presented data on the statistical distribution of the shortest, the long

Chairman Thank you very much. Is there any thing we have still missed out?

Hinchcliffe I would like to add serology and haematology In two consecutive series of one hundred patients, one case in each had leu kaemia presenting in vertigo

Chairman Let us just ask for a show of hands. Serology and haematology Those who agree this should be done? Your point is well taken

I want now to direct the discussion to con sider the minimum period of observation What I had in mind here is whether you can make up your mind on just one examination that the case is one of Ménière's disease and suitable for inclusion in the experimental series. Do you have to observe him for a period of time first? In some of these trials the pa tients were observed beforehand for long per iods. May I have suggestions please, from those who this afternoon presented papers on thera peutic trials, as to what they regard as a minimum period of observation before includ ing a particular patient in a trial.

Bertrand I would like to have these aspects taken into consideration first, whatever med ical treatment is used, the patient is not con sidered cured but controlled. The second aspect is that I believe that a patient can be included in a study immediately after his first visit Finally that it must be considered very haz ardous to give results relating only to three or even six or eight months of treatment.

Chairman We will be coming to your third point later What we must discuss now is be forehand. We have a suggestion here that once you have investigated the patient there is no need to wait any longer and observe him for a period of time Is there anyone who disagrees with that? No The next point is should you subdivide your patients into groups? The thing that I have in mind is this question of early and late cases. With the early cases you can perhaps look at all the facets of the treatment and the trial the effects on tinnitus, vertigo and deafness Whilst later on in the disease probably the vertigo is the only thing on which you may get useful results. Is it the general feeling that one should subdivide in this way or should you simply establish that each is a case of Ménière's disease in some particular stage and then lump all cases together?

Bertrand The patients which were included in my study were divided into three groups. The first group included the patients in the early stage of the disease in which, on at least one occasion there was a neuro-sensorial hear ing loss which hearing loss can still revert back to normal hearing. Into the second group I classified those patients who in addition to the the symptomatology present between the ver tiginous crises, had a permanent hearing loss or a permanent diminution of vestibular func tion Finally in a third group I have classi-fied those cases who present severe vertiginous crises and are under consideration for surgery Statistically patients in Group I have a higher percentage of control than those of Group II and those of Group II higher than those of Group III. Patients presenting with Ménière's disease could probably be classified in more groups than three but it would be I believe, difficult to obtain an objective classification

Chairman. I think you have with your study which is a very large-scale one and long-term as well something approaching the ideal. When you have got such large numbers, then I think you should subdivide there is no doubt about that. But we may need a practical compromise for smaller trials. Is it essential to pick groups which are all early and reversible or all mod-erate or all severe? Or can you simply take 10 or 20 cases which may be somewhat hetero-geneous with respect to stage or severity?

Wilmot Again I agree entirely with Dr Bert rand. I think we should have these three grades and that we should all think in these terms, even if we are collecting only a small number

You can still do your analysis of the whole group, but later if you have them sub-divided in this way you can, as you go along, collect more and more and eventually analyse each sub-division separately. I would go along with Dr Bertrand on this and say that we should have a definite method of grading along exactly the lines that he said.

Flynn. I also would agree with Dr Bertrand and Dr Wilmot but I would go a stage further especially if very small numbers are involved in a controlled trial because if you have random allocation to one of two or more treatments, with small numbers you have a very good chance that you may not have comparable groups. You may run into trouble despite the fact that everything was double-blind. For instance, if you have ten patients in one group and ten patients in the other group in the first group you might have eight who are in the early and reversible stage of the disease and in the second group eight who are in a late stage of the disease. This is something that you cannot predict and something you cannot avoid, unless you select and categorize the patients before you allocate them to a form of treatment.

Chairman. And you have a different statistical plan for each of these sub-groups? You allocate them to a sub-group and then, according to the sub-group, you would give each patient either placebo or drug according to some pre-arranged plan?

Flynn. Yes

Chairman. That seems to be a very sensible precaution.

Hinchcliffe. I would not agree that one should restrict the number of grades in one's assessment of severity to three. It would be better to use more grades of severity. It has been shown that, even if one wants to come out with three grades eventually, more precision can be achieved by asking the observer to use a 9-point scale than collapsing results to give a 3-point scale.

Chairman. In any kind of experiment one ends up by adding, adding, adding to it. I recall how I used to battle with our statistician in deciding what number of subjects to plan for. She always seemed to double the number I thought of as enough, but I knew she was going to do that so I quartered the number I thought she would ask for and so on. Thus, experimental decision is so often a question of practical compromise.

Coming back now to our topic, I think the ideal is to have three groups, and a separate statistical plan for each of these groups. But is there any practical compromise that could be suggested here for smaller trials? Well, I think the answer is simply to take your patients, classify them, and present results for each class or grade separately. But unless you are going for a relatively large study I do not think you could follow your point, Dr Flynn, very easily because you would then need a minimum of say 30 patients or something of that sort. You would do that if you can, but only if your study is big enough.

We come now to the question of controls. This either involves placebo treatment, or the history of that particular patient before he was included in the trial and came under treatment, or simply a comparison with the known, if it be known, natural course of Ménière's disease aiming to show that the expected progress would be such and such and your treatment has modified it and made it something different. The first question then is whether you can compare treated results with the known history of Ménière's disease and use that as the control? My own feeling is that the course of Ménière's disease is too variable for this.

Hinchcliffe. No Mr Chairman, you may remember that I have presented data on the statistical distribution of the shortest, the long-

est and the "average" episodes of not only the duration of vertigo but also of the intervals between episodes. These easily measured parameters could be used to show the effects of treatments whether we use the norms that we have already established, or others.

Chairman. So you feel it could be done It would be an acceptable way provided you explain what you have done

Hinchcliffe Yes!

Chairman And for that matter this would also go for any comparison with the patient's own history Now how about comparison with other therapeutic trials? I am thinking of the case where somebody else has published results with a different method of treatment, but using the same criteria of diagnosis and the same general format of trial. Say for example he had shown that 25% of the patients improved and the majority were not affected in your trial with another drug you find that 35% were improved. Can this be accepted as a valid comparison indicating that your drug is the better one? Have we yet got to a stage of definition of trials, particularly in Ménière's disease where you can do this sort of thing? My own feeling is that you have not. I think the variation between individual patients which have been selected for trials, however strict your criteria is so wide that you cannot compare your 35% success with somebody else's 25% If you get 95% and he gets 15% it is all right but fairly narrow comparisons of statistics are just not valid in this particular disorder I think the best you can hope for is to show that the thing is either ineffective slightly beneficial, moderately beneficial, or highly beneficial

Bertrand Certainly the comparison from one author to another is difficult and even hazardous in such a syndrome as Ménière's. However if the same author does a drug evaluation in a similar manner with two different drugs, he can compare the results obtained with either drug both for the clinical evaluation as for the objective tests. An example of this can be obtained from the results we obtained from the study with thiethylperazine in which it was noted that the effect of this medication produces a severe diminution of the vestibular response, as compared to the study done with betahistine HCl which demonstrated an increase of the vestibular response in the early stage of the treatment. Objective tests done on a patient, such as recorded by ENG can be analyzed and compared by the same author from one drug study to another or even from one laboratory to another if the same techniques and methods of analysis are used.

Chairman Obviously you can apply statistical tests to the results of one trial compared with another if the results are presented in the same format So subject to certain restrictions on sampling criteria it would seem useful and valid to compare one Ménière's syndrome drug with another even though tested in different trials with different patients.

Flynn I would like to say it depends on what it is that you are trying to prove when comparing the effects of one drug with another or with any other form of treatment. For example you can analyse the results from a trial which you have carried out yourself with one form of treatment and compare these results with those of another form of treatment, and convince yourself and many others that there is a difference between the two forms of treatment But as Dr Hinchcliffe pointed out, there is always going to be someone who will pick holes in it for a number of reasons. If we are trying to design a trial which proves or demonstrates without any doubt the efficacy of a treatment, then I think that to compare the results of one trial with another trial, which was done at a different time will always be open to criticism This also applies to any evaluation of the response to treatment if it is

compared only with the pre-treatment history of the patient.

Chairman. Coming to the question of double-blind trials, the thing that worries me is a doubt as to how blind they really are. I was not thinking so much of the experimenter's point of view but rather of the patient's point of view. I suspect that they can fairly quickly find out which drugs they are having or whether the drug has been changed. If it is a capsule, they only need to bite it on one occasion, or have a small leakage and there is a difference of taste; or maybe they notice some side-effect or other effect from a particular drug. I would like to ask those who have carried out these trials what their experiences may have been? Do they really feel that the patients had no idea at all which drug they were taking, or that they were taking something different on some occasions?

Flynn. As you said, it depends on the side-effects of the drug. Usually I think, the pharmacist who makes the placebo tablet tries to make it identical in as many ways as possible. One pharmaceutical company even claims that their placebos burn with the same coloured flame as the active tablets. But of course if you have a drug which has side-effects, then the patient can often distinguish a difference during two treatment periods. It is impossible or very difficult to find out if he does know or does not know. But the physician certainly should not know unless side-effects or clear therapeutic effects occur.

Bertrand. Double-blind study was started with betahistine HCl and it was impossible to determine at either the first or the second visit whether the subjects were receiving the drug or the placebo. This was not the case with the study with thiethylperazine. In that double-blind study, in which the patients were given either the drug or a placebo, the physician could determine by the questioning whether the subject was having the drug or a placebo, because of the frequency of side-effects which were present with that drug.

Chairman. In a double-blind trial, is it essential that the patient should not know that such a trial is going on and that there are two forms of tablet being given? Or should the patient be told? Should he be asked if he will participate in such a trial? This is really coming on to the ethics of drug trials, but I would like to take this point first.

Bertrand. I think that if the patient knows that he is on a double-blind trial, and that if he gets the active drug in the first part and he still gets one or two crises, he may start thinking "I am getting the placebo". Then, either he won't keep on taking it or you are introducing a psychological aspect. I think you are completely destroying the value of the double-blind technique in a disease such as Ménière's disease if the patient knows that he may be receiving a placebo. I do not think there is anything wrong with giving a placebo to a patient: the placebo-treatment in Ménière's disease exists in its own right and this is why I do not think it necessary to tell the patient.

Frew. In England this ethical standpoint has been a source of worry to many people for a long time, and only recently the Royal College of Physicians suggested that every hospital which engages in research should set up an ethical committee. We, at the present moment, are not allowed to carry out any form of trial without satisfying this committee that such a trial is not going to cause any damage to the patient.

Chairman. Does the committee insist on the patient being told, and asked if he would co-operate in the trial?

Frew. No. But I was referring to general principles of ethics.

est, and the "average" episodes of not only the duration of vertigo but also of the intervals between episodes. These easily measured parameters could be used to show the effects of treatments, whether we use the norms that we have already established or others.

Chairman So you feel it could be done It would be an acceptable way provided you explain what you have done

Hinchcliffe Yes!

Chairman And for that matter this would also go for any comparison with the patient s own history Now how about comparison with other therapeutic trials? I am thinking of the case where somebody else has published results with a different method of treatment, but using the same criteria of diagnosis and the same general format of trial Say for example, he had shown that 25% of the patients improved and the majority were not affected in your trial with another drug you find that 35 were improved Can this be accepted as a valid comparison indicating that your drug is the better one? Have we yet got to a stage of definition of trials, particularly in Ménière s disease where you can do this sort of thing? My own feeling is that you have not I think the variation between individual patients which have been selected for trials, however strict your criteria is so wide that you cannot compare your 35% success with somebody else s 25% If you get 95% and he gets 15% it is all right but fairly narrow comparisons of statistics are just not valid in this particular disorder I think the best you can hope for is to show that the thing is either ineffective slightly beneficial, moderately beneficial or highly beneficial

Bertrand Certainly the comparison from one author to another is difficult and even hazardous in such a syndrome as Ménière s. However if the same author does a drug evaluation in a similar manner with two different drugs, he can compare the results obtained with either drug both for the clinical evaluation as for the objective tests. An example of this can be obtained from the results we obtained from the study with thiethylperazine, in which it was noted that the effect of this medication produces a severe *diminution of* the vestibular response as compared to the study done with betahistine HCl which demonstrated an increase of the vestibular response in the early stage of the treatment. Objective tests done on a patient such as recorded by ENG can be analyzed and compared by the same author from one drug study to another or even from one laboratory to another if the same techniques and methods of analysis are used.

Chairman Obviously you can apply statistical tests to the results of one trial compared with another if the results are presented in the same format. So subject to certain restrictions on sampling criteria, it would seem useful and valid to compare one Ménière s syndrome drug with another even though tested in different trials with different patients.

Flynn I would like to say it depends on what it is that you are trying to prove when comparing the effects of one drug with another or with any other form of treatment For example, you can analyse the results from a trial which you have carried out yourself with one form of treatment and compare these results with those of another form of treatment, and convince yourself and many others that there is a difference between the two forms of treatment But as Dr Hinchcliffe pointed out, there is always going to be someone who will pick holes in it for a number of reasons. If we are trying to design a trial which proves or demonstrates without any doubt the efficacy of a treatment, then I think that to compare the results of one trial with another trial, which was done at a different time will always be open to criticism *This also applies to any* evaluation of the response to treatment if it is

is whether in Ménière's disease he should be told that at some stage he is going to have an inactive preparation or placebo.

Hinchcliffe. Could I perhaps suggest a way how we might resolve our dilemma? I think it was Bradford Hill who remarked "Whenever you do anything as regards treatment in medicine, if you do not do a controlled trial, then you really do an uncontrolled trial" So if we do not tell patients whenever we are doing an uncontrolled trial on them, which we do not, why should we tell them when we are doing a controlled trial?

Bertrand. I do not think that you should tell the patient that you are putting him on a double-blind study because of the psychological aspects to be considered in Ménière's disease and of the association of spontaneous remission which exists with this disease. However *all* of the patients are advised that they are on a drug trial evaluation and as already mentioned by Mr Frew such drug-trial evaluations in our hospital must be approved by a committee set up for such evaluation or such research. Therefore, we only advise our patient that he is on a trial medication, and we do not advise him that he will at one time or another receive a placebo especially when treating such pathology as Ménière's disease or Ménière's syndrome

Chairman. I will try to summarize this although I am still in something of a dilemma, in spite of Dr Hinchcliffe's contribution. Tell the patient that he is taking part in a trial agreed. But do you tell him that he may at some time have a placebo or not? My personal feeling is that you need not, if you are quite convinced in your mind that you are not withholding something which would be of value to him. But I think there may be some people here who do not even hold with that. Am I going too far for you to agree?

Roumga. No, I can agree with your summary because you are speaking now about Ménière's disease or Ménière's syndrome and I must admit that to my knowledge there are no well-controlled studies at this moment indicating that some drug is effective in this disease. So, especially in this case I do not think that you really withhold from the patient anything. So you can tell him he is participating in a trial and indeed, in this case, compare an active drug with a placebo. But I must repeat the words of Dr Geuens again that it is very possible to compare the *new* treatment with an old treatment, the best so far in your hands

Chairman. I would now like to consider the question of what period of observation is needed? Now I talked about cures earlier on, but we have had a very much better word suggested, in that we should be talking about control of the disease, not cure of it. Control over what length of period?

Bertrand. One patient in our series had, after three years of continuous vertiginous crises which completely incapacited him, a complete spontaneous remission for a period of 17 years. When evaluating the follow-up of a medical treatment for a Ménière's patient, when he asks the question "Will I get any more dizziness?" the only answer which can be given is that "The next crisis may come in a week, in a month, two months, five years from now or maybe never" I am inclined to compare this disease to something like diabetes. It is an easy thing to explain to a patient that diabetic patients are never cured, but may be controlled by various treatments. This is our objective, whether it may be a visit once a year to the doctor talk to him get a little psychotherapy or some medication, or an active treatment such as intravenous histamine. For practical purposes, however I think that we should take at least *five* years as the criterion: this would be a very good one but it is not a definite one as spontaneous remissions have occurred after periods longer than *five* years. Five year periods could be used in the same

Chairman On the general principle I quite agree Does anyone here feel that the patient has to be told? Or do you agree with Dr Bertrand that this is not necessary in fact that it would destroy the value of the trial if the patient does know that he is partaking in one?

Geuens I think it depends on whether the doctor himself believes that there exists an effective treatment If the doctor believes that there is an effective treatment, he should tell the patient that he is on a double blind trial, because in his mind he is withholding something from the patient So, when he believes that the drug is active he should not use a placebo but he could use another drug when one is available, that he thinks is next to or as active as the one he is studying

Chairman After what we heard in this morning's papers I do not think there need be anyone who need worry about this with Ménière's disease I do not think with the possible exception of Serc, that they are withholding anything which the patient should definitely be having and, if we are considering trials of Serc, that answers its own question.

In summary it is undesirable to tell the patient everything, unless for ethical reasons concerned with the fact that you may be withholding a treatment which you feel is likely to be beneficial under these circumstances, you should tell him Is that summarised all right? Yes.

We come now to the form of therapeutic trial and the ethical standpoints. Quite a lot of lively arguments came up during the tea interval as to a practical compromise here Whether you can or cannot use placebos, and what the form of the trial should be

Menon I agree with Dr Bertrand that in Ménière's disease there is no necessity really to tell the patient that he is on a double-blind trial. On the other hand, it is quite another problem, which I think should be brought forward, whether one should use placebo to compare with the drug being evaluated or whether the evaluation must always be with another allegedly active drug I think there must be different points of view as to whether the placebo should be used or not. And I would like to hear some other opinions on this.

Rosinga. I think we must realize that when you do a trial with drugs which may or may not be effective you are doing experiments in man After the Nürnberg-trial and the Declaration of Helsinki I think that in principle it is only ethical to tell the patient that he is participating in a trial When you do not I think you are not in agreement with the Declaration of Helsinki But of course there are sometimes difficulties that may arise from this policy and therefore I can only speak of the principle It is our policy as a matter of fact in this company to instruct the investigator to tell the patients that they are participating in a trial. I think that is really the only way you should do it

Chairman. It is a question, if you are the physician in charge of examining your own conscience on whether to withhold a drug or not But if having examined your conscience in all honesty you feel that you are not hazarding the patient, his health his general wellbeing or anything else, by conducting a particular form of trial, then I would have though that in spite of the Nürnberg-trials and the Declaration that followed, your conduct was correct. It is a question of giving positive thought to and following the dictates of your own conscience.

Menon I entirely agree with Dr Rosinga The question here is not whether the patient is informed that he is participating in a trial, but whether he should be told that he is going to have a placebo at some stage of the trial. Of course every patient I believe must be informed that he is participating in a trial involving the evaluation of drugs. I am sure most patients realise this anyway The question

is whether in Ménière's disease he should be told that at some stage he is going to have an inactive preparation or placebo.

Hinchcliffe Could I perhaps suggest a way how we might resolve our dilemma? I think it was Bradford Hill who remarked "Whenever you do anything as regards treatment in medicine if you do not do a controlled trial, then you really do an uncontrolled trial" So if we do not tell patients whenever we are doing an uncontrolled trial on them, which we do not, why should we tell them when we are doing a controlled trial?

Bertrand. I do not think that you should tell the patient that you are putting him on a double-blind study because of the psychological aspects to be considered in Ménière s disease and of the association of spontaneous remission which exists with this disease. However all of the patients are advised that they are on a drug-trial evaluation and as already mentioned by Mr Frew such drug-trial evaluations in our hospital must be approved by a committee set up for such evaluation or such research Therefore we only advise our patient that he is on a trial medication, and we do not advise him that he will at one time or another receive a placebo, especially when treating such pathology as Ménière s disease or Ménière s syndrome.

Chairman. I will try to summarize this although I am still in something of a dilemma, in spite of Dr Hinchcliffe s contribution Tell the patient that he is taking part in a trial, agreed But do you tell him that he may at some time have a placebo, or not? My personal feeling is that you need not, if you are quite convinced in your mind that you are not withholding something which would be of value to him. But I think there may be some people here who do not even hold with that. Am I going too far for you to agree?

Rosinga No, I can agree with your summary because you are speaking now about Ménière s disease or Ménière s syndrome and I must admit that to my knowledge there are no well-controlled studies at this moment indicating that some drug is effective in this disease. So especially in this case, I do not think that you really withhold from the patient anything. So you can tell him he is participating in a trial and indeed, in this case, compare an active drug with a placebo. But I must repeat the words of Dr Geuens again, that it is very possible to compare the new treatment with an old treatment, the best so far in your hands.

Chairman. I would now like to consider the question of what period of observation is needed? Now I talked about cures earlier on, but we have had a very much better word suggested, in that we should be talking about control of the disease, not cure of it. Control over what length of period?

Bertrand One patient in our series had, after three years of continuous vertiginous crises which completely incapacited him, a complete spontaneous remission for a period of 17 years. When evaluating the follow-up of a medical treatment for a Ménière s patient, when he asks the question Will I get any more dizziness?" the only answer which can be given is that "The next crisis may come in a week, in a month, two months, five years from now or maybe never" I am inclined to compare this disease to something like diabetes. After the Nürnberg trial and the Declaration of Helsinki, I think that in principle it is only ethical to tell the patient that he is participating in a trial When you do not, I think you are not in agreement with the Declaration of Helsinki. But of course there are sometimes difficulties that may arise from this policy and therefore I can only speak of the principle It is our policy as a matter of fact, in this company to instruct the investigator to tell the patients that they are participating in a trial I think that is really the only way you should do it

Chairman It is a question if you are the physician in charge of examining your own conscience on whether to withhold a drug or not. But if having examined your conscience in all honesty you feel that you are not hazarding the patient, his health, his general wellbeing or anything else, by conducting a particular form of trial then I would have though that in spite of the Nürnberg trials and the Declaration that followed your conduct was correct It is a question of giving positive thought to and following the dictates of your own conscience.

Menon I entirely agree with Dr Rosinga. The question here is not whether the patient is informed that he is participating in a trial but whether he should be told that he is going to have a placebo at some stage of the trial. Of course every patient I believe, must be informed that he is participating in a trial involving the evaluation of drugs. I am sure most patients realise this anyway The question

is whether in Ménière's disease he should be told that at some stage he is going to have an inactive preparation or placebo.

Hinchcliffe Could I perhaps suggest a way how we might resolve our dilemma? I think it was Bradford Hill who remarked "Whenever you do anything as regards treatment in medicine, if you do not do a controlled trial, then you really do an uncontrolled trial" So if we do not tell patients whenever we are doing an uncontrolled trial on them, which we do not, why should we tell them when we are doing a controlled trial?

Bertrand. I do not think that you should tell the patient that you are putting him on a double-blind study because of the psychological aspects to be considered in Ménière's disease and of the association of spontaneous remission which exists with this disease. However all of the patients are advised that they are on a drug-trial evaluation and as already mentioned by Mr Frew such drug-trial evaluations in our hospital must be approved by a committee set up for such evaluation or such research Therefore, we only advise our patient that he is on a trial medication, and we do not advise him that he will at one time or another receive a placebo especially when treating such pathology as Ménière's disease or Ménière's syndrome.

Chairman I will try to summarize this although I am still in something of a dilemma, in spite of Dr Hinchcliffe's contribution Tell the patient that he is taking part in a trial, agreed But do you tell him that he may at some time have a placebo or not? My personal feeling is that you need not, if you are quite convinced in your mind that you are not withholding something which would be of value to him But I think there may be some people here who do not even hold with that. Am I going too far for you to agree?

Rosingo No I can agree with your summary because you are speaking now about Ménière's disease or Ménière's syndrome and I must admit that to my knowledge there are no well-controlled studies at this moment indicating that some drug is effective in this disease So, especially in this case, I do not think that you really withhold from the patient anything. So you can tell him he is participating in a trial and indeed, in this case, compare an active drug with a placebo But I must repeat the words of Dr Geuens again, that it is very possible to compare the new treatment with an old treatment, the best so far in your hands

Chairman. I would now like to consider the question of what period of observation is needed? Now I talked about cures earlier on, but we have had a very much better word suggested, in that we should be talking about control of the disease, not cure of it. Control over what length of period?

Bertrand. One patient in our series had, after three years of continuous vertiginous crises which completely incapacited him, a complete spontaneous remission for a period of 17 years. When evaluating the follow-up of a medical treatment for a Ménière's patient, when he asks the question "Will I get any more dizziness?" the only answer which can be given is that "The next crisis may come in a week, in a month, two months, five years from now or maybe never" I am inclined to compare this disease to something like diabetes. It is an easy thing to explain to a patient that diabetic patients are never cured, but may be controlled by various treatments. This is our objective whether it may be a visit once a year to the doctor talk to him, get a little psychotherapy or some medication, or an active treatment such as intravenous histamine. For practical purposes, however I think that we should take at least five years as the criterion. this would be a very good one but it is not a definite one as spontaneous remissions have occurred after periods longer than five years. Five year periods could be used in the same

manner as a five year cure in cancer is used which does not mean that a patient does not have any more cancer because he has survived five years since the original diagnosis of that pathology

Chairman. Of course with cancer it is a question of follow up after some relatively short period of treatment. But with Ménière's disease it presumably is a question of continued treatment Do I understand that you would like to have the patients on this drug or that regime for a period of five years, and then compare their symptomatology and objective signs at the end of that period with those at the start of treatment or with the otherwise expected progression of the disease?

Bertrand. At the present time if there is control after one or two years of medication I will stop the medication but, should the vertiginous crises reappear I would ask the patient to start taking the medication again and consult his referring physician In any case since this is a disease which can recur I always make it a point that they should have a review at yearly intervals for a few years.

Chairman At this point I think we need some clarification on our discussions. If one is really looking for the controlling effect of a treatment surely you can look over quite a short period of time? If you are looking for a "cure then you need this long follow up period to be sure that there has been a "cure" or reasonably sure that there has been a cure" in the majority of patients, anyhow Of course many of the surgical treatments of Ménière's disease are aimed at long term results. It is hoped that one operation will settle the patient for many years, if not permanently Perhaps this question of five year observation really refers to the one-off surgical type of treatment rather than drug treatment aimed to control If you feel that the drug treatment is going to do something perhaps by improving the microcirculation to permanently correct something that was wrong, then obviously you have got to do a long-term follow-up to see if this temporary improvement is maintained or not. But I do not think anyone here has that idea with respect to treatment with for example, Serc or with any other drug It is not going to produce a permanent cure but it may control the symptoms at the time of administration If they recur then presumably you give the drug again

Wilmot Dr Bertrand and I have shown that there is an effect upon vestibular function of giving this drug Now it would be nice to know certain specific things about this. First, what is the minimum dosage with which we could produce this improvement. Secondly how long does this objective change in vestibular function last after the cessation of treatment. These are relatively short term goals, which could be found out quite soon There are a lot of studies like this which would help because the aim as you just emphasized, is not to keep people on treatment for the rest of their lives, but to know how often to treat them and how long the effect of the drug is likely to act after the treatment is stopped. Dr Bertrand's study in depth or at length should give us further information on this, but we can also do these short term studies.

Hinchcliffe Is it not now appropriate to discuss what form of therapeutic trial should be undertaken? I would not accept that Ménière's disorder is such a peculiar disorder that it is impossible to subject it to a double-blind cross-over trial. I would also add that there are types of therapeutic trials, e.g. sequential analysis, where it is possible to stop the trial as soon as the point is reached where it could be known that one method of treatment is superior to another

Could I also mention at this point very briefly my own practical experiences when I started double-blind trials in Ménière's disorder some years ago? When patients returned for follow-up, I might ask "Well how are you?"

I am fine. In fact I was able to stop the drug after two days" Or else the patient would say "Oh, by the way it was alright for me to carry on taking the drugs that my own doctor gave me wasn t it?" It was indeed exasperating.

Finally might I ask two questions. First, should we throw out the placebo-responders? And secondly should we use an indicator e g. a substance in the drugs that would be detectable in the urine, which would confirm that the patient had indeed taken the drugs?

Chairman. I think we should add that to the list of optional extras. It would be good if you could do them, but perhaps it is not absolutely essential.

Hinchcliffe An initial placebo-responder trial should be considered very seriously in planning this programme.

Flynn This problem is not restricted to trials in Menière s disease only but to any clinical trials. Only yesterday I came across such a study not in patients with Ménière s disease, in which more than 100 patients were followed. They were given a medicine containing an indicator and urine samples were collected during several months of follow-up they were also asked to bring back the bottles with any remaining medicine in them Of course some patients get up to all sorts of tricks, once they suspect that you are counting how many tablets are coming back They calculate how many they should have taken and then throw these away And it is also possible that intelligent patients can guess that you want a urine sample in order to check whether he has taken the treatment But what was outstanding from the study was that only in ten patients was there disagreement between the urinary results and the results from counting the returned bottles with contents Of course this was not in Ménière's disease, and maybe Ménière s patients respond in a different way

Chairman. Thank you for stressing the importance of these features in the design of the therapeutical trial. You are supporting Dr Hinchcliffe s views and also his suggestion of having an initial trial for the placebo responders. Anyone disagree? No

There is also the possibility of doing double-blind parallel experiments, as distinct from the double-blind cross-over ones. If you find a cross-over is difficult you could perhaps do the trial in parallel, half the subjects having one treatment and half the subjects the other and then compare the two groups. Would that be acceptable?

Bertrand. Well, it would take too long to discuss that.

Chairman Yes, we are short of time now May I then raise very briefly the question of a let-out clause mentioned earlier this afternoon. How would you bring that into the format of a trial?

Flynn. The let-out clause was mentioned in connection with a further study by Dr Hommes. He could not agree to do a double-blind trial, originally with betahistine in Ménière s disease, because the patients were completely incapacitated and, although there had been failure of all treatments which had been applied, as has been stated today there are so many different types of treatment which he could have tried that it was not justifiable to treat them with placebo When it was discovered that almost all of the patients responded, it was thought that there was one way in which it could be confirmed whether this was or was not a real drug effect. And this was to stop the treatment in half of the patients, but without informing them that there had been a change in their therapy If you once informed them, they would immediately I am sure, have some kind of a relapse in their symptoms. But if the patients in the placebo group, not knowing the nature of the tablets, very rapidly develop a relapse of

symptoms but the patients in the betahistine group do not, this will permit one to immediately commence active treatment again in those relapses. In addition this permits one to observe whether or not treatment needs to be continued at the same time eliminating the psychological effect of stopping or changing the treatment

Chairman So the let-out clause would be for the experimenter to know about the change of treatment and to be free to adapt accordingly The patient would not be given any explanation of this?

Flynn No

Chairman Good, that was the point I wanted to cover I think we have covered most of the agenda for this discussion The post-treatment investigation I feel is simply a replica or near replica of the pre treatment investigation. As to the criteria of success or failure I do not think this is really relevant to this discussion. It would take too long anyway and it has been covered pretty well in the papers which have listed the tests and various investigations performed That concludes the panel discussion

SUMMARY OF PANEL DISCUSSION

(prepared, retrospectively by the Chairman)

The full text of the panel discussion on "How should a treatment of Ménière s syndrome be evaluated?" is given on the preceding pages, but it may help the reader who is contemplating carrying out a therapeutic trial in patients with this disorder to refer to the summary which follows.

Diagnosis of Ménière s disorder to be utilised in the patients

1 Classical triad of symptoms should be complete if possible but vertigo is the key symptom.
2. Homogeneity established statistically
3 A detailed medical history with (optionally) a personality inventory
4 A full neurological and cardiovascular examination with special emphasis on the cranial nerves, optic fundi gait and balance B P and pulse neck vessels, with (optionally) lumbar puncture
5 Audiological investigation by tuning fork tests, pure-tone a/c and b/c audiometry Békésy audiometry or tone decay tests, a recruitment test, and (preferably) speech audiometry
6 Vestibular investigation spontaneous nystagmus positional nystagmus, neck torsion nystagmus, caloric tests or rotation tests, (optionally) thermal vestibulometry
7 Radiology of skull (petrous bones) and cervical spine
8 Haematology (haemoglobin and cell count) and serology (W R. et al)

Classification of patients (into 3 stages)

1st stage early type remissions (= reversible) analyse for a variety of symptoms,

e.g. deafness, tinnitus, vertigo, headache.

2nd stage- persistent hearing loss, slight vestibular hypofunction.

3rd stage- advanced hearing loss and vestibular hypofunction analyse for control of vertigo.

Form of therapeutic trial

Double-blind trial with placebo or another active drug: cross-over or parallel.

Preferably an initial trial for placebo-responders.

Inform the patient that he is on a drug trial, but not that there is a placebo. Placebos justifiable if (i) you are sure you are not withholding a treatment of value to him and (ii) a let-out clause by which the experimenter can modify the treatment if the placebo causes a serious relapse.

Short periods of treatment and placebo to determine the immediate controlling effects of the drug, or a long-term study with follow up over many years to ascertain the "five year cure" rate.

Analysis principally by frequency and severity of vertiginous attacks, also by audiometric and vestibulometric changes, and by other symptoms.

I Introduction

Otosclerosis is one of the most carefully studied diseases of the ear Hearing loss caused by what is now called stapedial ankylosis was described by Valsalva as early as 1735

So far the etiology of otosclerosis has remained obscure in spite of the numerous theories suggested Delayed physiological development, inflammatory processes, cartilaginous deposits in the region of the fissula ante fenestram, disturbances in the blood supply mechanical stimuli, etc has been described as possible causes of otosclerosis. It is obvious that there are constitutional local and activating factors which are responsible for the development of otosclerotic foci either individually or jointly (Altman, 1962)

For the last few years the fundamental study of otosclerosis has principally been devoted to the histochemistry of otosclerotic foci A significant elevation in the activity of alkaline phosphatase and, on the other hand, an equally significant fall in the activity of lactic acid dehydrogenase have been revealed Some changes have also been shown in the matrix of the otosclerotic bone, for instance in the number and construction of the polysaccharides.

In addition to typical conductive hearing loss, patients suffering from otosclerosis also often have perceptive hearing loss. Cochlear lesions are considered to be due to secretions from the active otosclerotic foci which have found their way into the endolymph (Shambaugh, 1959)

Vestibular disturbances even appear in patients suffering from otosclerosis (Fisch, 1965) These may be derived from otosclerotic vascular changes due to the disease or from biochemical changes in the inner ear fluids.

Because the hearing loss in otosclerosis is dominant, otosclerotic patients have not been examined for other disorders associated with otosclerosis as carefully as for hearing. Unsteadiness in walking and stopping can, however frequently be observed in these patients. In electronystagmographic investigations, findings, obviously differing from the normal, have been revealed (Meurman et al., 1969) It is obvious that further studies of these changes will throw additional light on the general view of otosclerosis.

I Introduction

Otosclerosis is one of the most carefully studied diseases of the ear Hearing loss caused by what is now called stapedial ankylosis was described by Valsalva as early as 1735

So far the etiology of otosclerosis has remained obscure in spite of the numerous theories suggested Delayed physiological development, inflammatory processes, cartilaginous deposits in the region of the fissula ante fenestram, disturbances in the blood supply mechanical stimuli, etc. have been described as possible causes of otosclerosis It is obvious that there are constitutional, local and activating factors which are responsible for the development of otosclerotic foci either individually or jointly (Altman, 1962)

For the last few years the fundamental study of otosclerosis has principally been devoted to the histochemistry of otosclerotic foci A significant elevation in the activity of alkaline phosphatase and, on the other hand, an equally significant fall in the activity of lactic acid dehydrogenase have been revealed Some changes have also been shown in the matrix of the otosclerotic bone, for instance in the number and construction of the polysaccharides

In addition to typical conductive hearing loss, patients suffering from otosclerosis also often have perceptive hearing loss. Cochlear lesions are considered to be due to secretions from the active otosclerotic foci which have found their way into the endolymph (Shambaugh, 1959)

Vestibular disturbances even appear in patients suffering from otosclerosis (Finch, 1965) These may be derived from otosclerotic vascular changes due to the disease or from biochemical changes in the inner ear fluids

Because the hearing loss in otosclerosis is dominant, otosclerotic patients have not been examined for other disorders associated with otosclerosis as carefully as for hearing Unsteadiness in walking and stopping can, however frequently be observed in these patients. In electronystagmographic investigations, findings, obviously differing from the normal, have been revealed (Meurman et al., 1969) It is obvious that further studies of these changes will throw additional light on the general view of otosclerosis.

II The aim of the study

The aim of this investigation was to clarify the vestibular disturbances in patients suffering from otosclerosis. The following main points were studied

1. Does positional nystagmus occur in these patients?
2. Do the findings of caloric tests differ from the normal reactions?
3. Is there any possible correlation between hearing impairment and electronystagmographic findings?
4. What is the threshold of angular acceleration and deceleration in these patients, and does the threshold deviate from the normal values?
5. Do the findings of post rotatory nystagmus differ from the normal results?

III Review of the literature

A. Occurrence of otosclerotic foci

The importance of distinguishing between clinical and histological otosclerosis must be emphasized in any comment on the incidence of otosclerosis Engstrom (1940) revealed histological otosclerosis on the temporal bones in 12 per cent of 200 autopsies On the other hand Guild (1944) demonstrated histological otosclerosis in only 8.3 per cent of 518 whites and 1 per cent of 482 negroes Clinical otosclerosis, on the other hand, can be found in about 1 per cent of the white population.

Otosclerosis usually involves both ears Yet the frequency of histologically unilateral otosclerosis in the series of unselected subjects has been established at as high as 30 per cent by Guild (1944) 25 per cent by Nylén 1949) 13 per cent by Cawthorne (1955) and 15 per cent by Larsson (1960)

The size of the otosclerotic foci observed in autopsies varies greatly from a microfocus, demonstrable only in the electron microscope to very large focus, replacing most of the labyrinthine capsule (Guild, 1944 Nylén, 1949 Beikert, 1965 Chevance et al 1969) The area of the labyrinthine capsule immediately in front of the oval window is known as the site of predilection of the otosclerotic focus The borders of the round window are also frequent sites for otosclerotic foci. A primary focus may however occur even in the stapes footplate, around the cochlea, near the internal auditory canal, or less often around the semicircular canals

The focus nearly always originates in the endochondral layer of the labyrinthine capsule extending in many cases into the periostal layers as far as the mucosa of the tympanic cavity and into the endostal layer of the endosteum of the labyrinth Protrusions into the tympanic cavity in the form of exostoses are frequent Less common are encroachments upon the lumen of the labyrinth Where the focus reaches the mucoperiosteum of the tympanum and the endosteum of the labyrinth, these show varying degrees of fibrous thickening and increased vascularity (Shambaugh, 1959)

Examinations of 2086 operated ears revealed that cochlear nerve involvement is present twice as often when otosclerotic foci are situated in the horizontal semicircular canal, compared with the frequency of the involvement when the canal is not affected (Seligman and Shambaugh, 1951) Histological otosclerosis is at any rate quite frequently asymptomatic. Most otosclerotic areas do not cause ankylosis of the stapes, even if located at the anterior margin of the oval window

In one patient suffering from the symptoms of Ménières disease the lateral semicircular canal was found at autopsy to be full of otosclerotic bone (Bretlau and Jorgensen, 1968)

B. Histological picture of otosclerosis

Otosclerosis is a disease of the bony labyrinthine capsule, frequently developing in areas where embryonic cartilage persists The pathological process is characterized by resorption of the normal bone, often around the blood vessels, and by the replacement of normal bone with cellular fibrous connective tissue. Areas undergoing active resorption are extensively vascularized

Wolf and Bellucci (1960) have suggested that some enzyme serves as the initiating factor of decalcification. Chevance et al (1961) suggested that the focus shows alkaline phosphatase during the first phase and the whole of the second phase until the bone is completely calcified. Alkaline phosphatase will then disappear The enzyme was extracellular except in osteoblasts where it was found to be intracellular Ricci (1962) observed that the activity of alkaline phosphatase increases in the focus He discovered

II The aim of the study

The aim of this investigation was to clarify the vestibular disturbances in patients suffering from otosclerosis. The following main points were studied

1. Does positional nystagmus occur in these patients?
2. Do the findings of caloric tests differ from the normal reactions?
3. Is there any possible correlation between hearing impairment and electronystagmographic findings?
4. What is the threshold of angular acceleration and deceleration in these patients, and does the threshold deviate from the normal values?
5. Do the findings of post rotatory nystagmus differ from the normal results?

III Review of the literature

A. Occurrence of otosclerotic foci

The importance of distinguishing between clinical and histological otosclerosis must be emphasized in any comment on the incidence of otosclerosis Engstrom (1940) revealed histological otosclerosis on the temporal bones in 12 per cent of 200 autopsies. On the other hand Guild (1944) demonstrated histological otosclerosis in only 8,3 per cent of 518 whites and 1 per cent of 482 negroes Clinical otosclerosis, on the other hand, can be found in about 1 per cent of the whit population

Otosclerosis usually involves both ears Yet the frequency of histologically unilateral otosclerosis in the series of unselected subjects has been established t as high as 30 per cent by Guild (1944) 25 per cent by Nylén 1949) 13 per cent by Cawthorne (1955) and 15 per cent by Larsson (1960)

The size of the otosclerotic foci observed in autopsies varies greatly from a microfocus, demonstrable only in the electron microscope to a ery large focus, replacing most of the labyrinthine capsule (Guild, 1944 Nylén, 1949 Beikert, 1965 Chevance et al. 1969) The area of the labyrinthine capsule immediately in front of the oval window is known as the sit of predilection of the otosclerotic focus The borders of the round window are also frequent sites for otosclerotic foci. A primary focus may however occur even in the tapes footplate, around the cochlea, near the internal uditory canal or less ften around the semicircular canals

The focus nearly always originates in the endochondral layer of the labyrinthine capsule extending in many cases into the periostal layers as far as the mucosa of the tympanic cavity nd int the endostal layer of the endosteum of the labyrinth Protrusions int the tympanic cavity in the form of exostoses are frequent Less common are encroachments upon the lumen of the labyrinth. Where the focus reaches the mucoperiosteum of the tympanum and the endosteum of the labyrinth, these show varying degrees of fibrous thickening and increased vascularity (Shambaugh, 1959)

Examinations of 2 086 operated ears re ealed that cochlear nerve involvement is present twice as often when otosclerotic foci are situated in the horizontal semicircular canal, compared w th the frequency of the involvement when the canal is not af fected (Seligman and Shambaugh, 1951) Hist logical otosclerosis is at any rate quite frequently asymptomatic. Most otosclerotic areas do not cause ankylosis of the stapes, even if located at the anterior margin of the oval window

In one patient suffering from the symptoms of Ménières disease the lateral semicircular canal was found at autopsy to be full f otosclerotic bone (Bretlau and Jörgensen, 1968)

B. Histological picture of otosclerosis

Otosclerosis is a disease of the bony labyrinthine capsule, frequently developing in areas where embryonic cartilage persists. The pathological process is characterized by resorption of the normal bone, often around the blood essels, and by the replacement of normal bone with cellular fibrous connective tissue Areas undergoing active resorption are extensively ascularized.

Wolf and Bellucci (1960) ha e suggested that some enzyme serves as the initiating factor of decalcification. Chevance et al (1961) suggested that the focus shows alkaline phosphatase during the first phase and the whole of the second phase until the bone is completely calcified. Alkaline phosphatase will then disappear The enzyme was extracellulary except in osteoblasts where it was found to be intracell lar Ricci (1962) observed that the activity of alkaline phosphatase increases in the focus He discovered

alkaline phosphatase in both the osteocytes and the ground substance Abnormal accumulation of mucopolysaccharides in the otosclerotic focus was also observed Ricci suggested that the primary cause of otosclerosis was a certain change in the ground substance. Alberti and Tarkkanen (1963) have shown that there is an increased amount of leucine aminopeptidase and non-specific esterases present in the otosclerotic lesions, particularly in the perivascular fibroblasts and the osteocytes.

The participation of vascular changes in the genesis of decalcification has also been proposed (Wolf and Lempert 1965) Ruedi (1964 1969) observed abnormal vascular connections between the membranous labyrinth and the focus. These take the form of a circumscribed increase in the vascular loops and a proliferation of the epithelium of the stria. It appears that this strial proliferation probably occurs as a result of a circulatory disturbance in the region of the cochlear branch of the internal auditory artery The circulatory disturbance is caused by vascular demands made by the actively growing otosclerotic deposit.

It has also been verified that there are microfoci between the focus and normal tissue demonstrable only under an electron microscope (Chevance et al. 1969) The endothelial cells of the capillary network of the focus were however found to be normal

C. Changes in the composition of the perilymph in association with otosclerosis

The nature of the origin of the perilymph has not yet been clarified The perilymph is assumed to be of an extracellular character with low potassium and high sodium concentration.

In 122 otosclerotic patients the perilymph and the serum showed the same frequency dispersion for the concentration of glucose, calcium, sodium, and potassium. The values of maximum lacticacid dehydrogenase activity in the serum and the perilymph did not differ The values were much higher in the serum and the perilymph than in the liquor The mean phosphate concentration of the perilymph was also higher than that in the serum (Schindler et al. 1965) In 15 patients suffering from severe otosclerosis the contents of the alfa and beta globuline fractions had reduced (Chládek and Opplt 1966) The latter established further that there was a distinct relationship between the range of the protein spectrum in the perilymph and the activity of otosclerosis (1968) A correlation between the increased potassium and protein values and the preoperative hearing impairment for the bone conduction at 4 000 Hz was statistically proved by 155 otosclerotic patients (Rüedi, 1965) No statistical correlation was, however evident between the increased potassium and protein values and the pre- or postoperative vestibular symptoms in otosclerotic patients. Alkaline phosphatase was also found in the perilymph of otosclerotic patients. The mean value was as high as 2,8 B.E. (Bodansky Einheiten = Bodansky Units) There is no alkaline phosphatase in the perilymph of a normal ear

D Vertigo and electronystagmographic findings in patients suffering from otosclerosis

a. Electronystagmography (ENG) and caloric tests

Studies of vestibular changes in otosclerotic patients are remarkably less frequent than those of other otosclerotic disorders. Before the ENG-era, disturbances in the vestibular system could only be verified in extremely few otosclerosis cases. Although 27 per cent of 77 patients declared anamnestically that they suffered from vertigo only five cases revealed deviations from the normal reactions in the caloric tests (Rasmussen, 1949) Likewise Hulk and Jongkees (1950) were unable to verify either spontaneous or positional nystagmus, on the one hand or deviations in the caloric tests on the other hand, when studying 50 patients, 30 per cent of whom declared anamnestically that they suffered from unsteadiness while walking and from fits of dizziness on stopping

Aschan et al. (1956) were also unable to verify any nystagmus in a clinical investigation with Frenzel's glasses on one patient who showed spontaneous nystagmus in the ENG recording Reinecken (1960) described some electronystagmographic findings in as

many as 25 per cent of patients ... from clinical otosclerosis before operation. Fisch (1965) manifested spontaneous nystagmus in eight and direction-determined positional nystagmus in seven cases of a total number of 52 patients, i.e. jointly 28,8 per cent of cases.

Meurman et al. (1969) found approximately the same percentage of nystagmus, but in the total 110 otosclerotic cases studied by them, there were only two cases with direction-changing positional nystagmus while the figure for direction-determined nystagmus was as high as 22. Twenty-three subjects in the same study of patients showed abnormalities in the caloric tests.

In eight patients the caloric excitability was found to be reduced in the poorer ear while six subjects revealed reduced caloric excitability in the better ear. Directional preponderance to the side of the worse ear was observed in six cases, while there were three cases with directional preponderance to the side of the better ear.

b. Rotatory tests

Since Barany's first introduction (1907) of rotatory tests, his original method has sustained several modifications. When the rotating chair was employed in the earliest period of the method, it was the sensation of turning during and after rotation that was calculated in the first place. The postrotatory nystagmus was also computed. The modern rotating chair enables us to produce very delicate and minute accelerations and decelerations. ENG too makes it possible to record most subtile divergences in nystagmus. This in turn permits more physiological irritation of the semicircular canals than before. As well as calculations of postrotatory nystagmus, computations of the thresholds of nystagmus made feasible by the modern rotating chair.

As early as 1875 Mach showed by torsion of two suspended wires that the threshold for sensation of acceleration varied between 2 and 3 °/sec². A more recent investigation indicates that the minimum perceptible acceleration when applying small accelerations of prolonged activity by means of torsion swing is as low as 0,5 °/sec² (van Egmond, Groen and Jongkees, 1949).

In the tests executed by employing the rotating chair Hilding (1953), de Vries and Schlerbeek (1953) and Roggeveen and Nijhoff (1956) showed that the threshold of minimum perceptible acceleration and deceleration varies from 0,25 °/sec² to 3,5 °/sec².

By utilizing an ENG recording of perrotatory nystagmus Montandon and Russbach (1956) have shown that the threshold of nystagmus and the sensation of turning is approximately 0,8 °/sec² in normal subjects, and this value applies to acceleration and deceleration. Decher (1965) however obtained somewhat lower threshold values, approximating 0.4 °/sec².

The intensity and duration of postrotatory nystagmus has been shown to be in linear relation to the speed of rotation before abrupt stopping (van Egmond et al. 1948, Aschan et al. 1952).

In patients suffering from otosclerosis, the threshold of sensing turning is raised (Hulk and Jongkees, 1948). Postrotatory nystagmus has been established as being of shorter duration in otosclerotic patients than in normal subjects (Rasmussen 1949). On the other hand, Purnanen has measured about the same duration of postrotatory nystagmus in otosclerotic patients as in normal subjects (1954), while the threshold of after-nystagmus in otosclerotic patients is raised (Hulk and Jongkees, 1948).

alkaline phosphatase in both the osteocytes and the ground substance. Abnormal accumulation of mucopolysaccharides in the otosclerotic focus was also observed. Ricci suggested that the primary cause of otosclerosis was a certain change in the ground substance. Alberti and Tarkkanen (1963) have shown that there is an increased amount of leucine aminopeptidase and non-specific esterases present in the otosclerotic lesions, particularly in the perivascular fibroblasts and the osteocytes.

The participation of vascular changes in the genesis of decalcification has also been proposed (Wolf and Lempert, 1965). Rüedi (1964, 1969) observed abnormal vascular connections between the membranous labyrinth and the focus. These take the form of a circumscribed increase in the vascular loops and a proliferation of the epithelium of the stria. It appears that this strial proliferation probably occurs as a result of a circulatory disturbance in the region of the cochlear branch of the internal auditory artery. The circulatory disturbance is caused by vascular demands made by the actively growing otosclerotic deposit.

It has also been verified that there are microfoci between the focus and normal tissue demonstrable only under an electron microscope (Chevance et al. 1969). The endothelial cells of the capillary network of the focus were however found to be normal.

C. Changes in the composition of the perilymph in association with otosclerosis

The nature of the origin of the perilymph has not yet been clarified. The perilymph is assumed to be of an extracellular character with low potassium and high sodium concentration.

In 122 otosclerotic patients the perilymph and the serum showed the same frequency dispersion for the concentration of glucose, calcium, sodium and potassium. The values of maximum lacticacid dehydrogenase activity in the serum and the perilymph did not differ. The values were much higher in the serum and the perilymph than in the liquor. The mean phosphate concentration of the perilymph was also higher than that in the serum (Schindler et al. 1965). In 15 patients suffering from severe otosclerosis the contents of the alfa and beta globuline fractions had reduced (Chládek and Opplt 1966). The latter established further that there was a distinct relationship between the range of the protein spectrum in the perilymph and the activity of otosclerosis (1968). A correlation between the increased potassium and protein values and the preoperative hearing impairment for the bone conduction at 4 000 Hz was statistically proved by 155 otosclerotic patients (Ruedi 1965). No statistical correlation was however evident between the increased potassium and protein values and the pre- or postoperative vestibular symptoms in otosclerotic patients. Alkaline phosphatase was also found in the perilymph of otosclerotic patients. The mean value was as high as 2.3 B.E. (Bodansky Einheiten = Bodansky Units). There is no alkaline phosphatase in the perilymph of a normal ear.

D. Vertigo and electronystagmographic findings in patients suffering from otosclerosis

a. Electronystagmography (ENG) and caloric tests

Studies of vestibular changes in otosclerotic patients are remarkably less frequent than those of other otosclerotic disorders. Before the ENG-era, disturbances in the vestibular system could only be verified in extremely few otosclerosis cases. Although 27 per cent of 77 patients declared anamnestically that they suffered from vertigo, only five cases revealed deviations from the normal reactions in the caloric tests (Rasmussen, 1949). Likewise Hulk and Jongkees (1950) were unable to verify either spontaneous or positional nystagmus on the one hand, or deviations in the caloric tests on the other hand when studying 50 patients, 30 per cent of whom declared anamnestically that they suffered from unsteadiness while walking and from fits of dizziness on stopping.

Aschan et al. (1956) were also unable to verify any nystagmus in a clinical investigation with Frenzel's glasses on one patient who showed spontaneous nystagmus in the ENG recording. Reinecken (1960) described some electronystagmographic findings in as

many as 25 per cent of patients suffering from clinical otosclerosis before operation. Fisch (1963) manifested spontaneous nystagmus in eight and direction-determined positional nystagmus in seven cases of a total number of 52 patients, i.e. jointly 28,8 per cent of cases.

Meurman et al. (1969) found approximately the same percentage of nystagmus, but in the total 110 otosclerotic cases studied by them, there were only two cases with direction-changing positional nystagmus while the figure for direction-determined nystagmus was as high as 22. Twenty three subjects in the same study of patients showed abnormalities in the caloric tests.

In eight patients the caloric excitability was found to be reduced in the poorer ear while six subjects revealed reduced caloric excitability in the better ear. Directional preponderance to the side of the worse ear was observed in six cases, while there were three cases with directional preponderance to the side of the better ear.

b. Rotatory tests

Since Barany's first introduction (1907) of rotatory tests, his original method has sustained several modifications. When the rotating chair was employed in the earliest period of the method, it was the sensation of turning during and after rotation that was calculated in the first place. The postrotatory nystagmus was also computed. The modern rotating chair enables us to produce very delicate and minute accelerations and decelerations. ENG, too, makes it possible to record most subtle divergences in nystagmus. This in turn permits a more physiological irritation of the semicircular canals than before. As well as calculations of postrotatory nystagmus, computations of the thresholds of nystagmus during acceleration and deceleration are made feasible by the modern rotating chair.

As early as 1875 Mach showed by torsion of two suspended wires that the threshold for sensation of acceleration varied between 2 and 3 °/sec². A more recent investigation indicates that the minimum perceptible acceleration when applying small accelerations of prolonged activity by means of torsion swing is as low as 0,5 °/sec² (van Egmond, Groen and Jongkees, 1949).

In the tests executed by employing the rotating chair Hilding (1953), de Vries and Schierbeek (1953) and Roggeveen and Nijhoff (1956) showed that the threshold of minimum perceptible acceleration and deceleration varies from 0,25 °/sec² to 3,5 °/sec².

By utilizing an ENG recording of perrotatory nystagmus Montandon and Russbach (1956) have shown that the threshold of nystagmus and the sensation of turning is approximately 0,8 °/sec² in normal subjects, and this value applies to acceleration and deceleration. Decher (1965) however obtained somewhat lower threshold values, approximating 0.4 °/sec².

The intensity and duration of postrotatory nystagmus has been shown to be in linear relation to the speed of rotation before abrupt stopping (van Egmond et al. 1948, Aschan et al. 1952).

In patients suffering from otosclerosis, the threshold of sensing turning is raised (Hulk and Jongkees, 1948). Postrotatory nystagmus has been established as being of shorter duration in otosclerotic patients than in normal subjects (Rasmussen 1949). On the other hand, Pulmanen has measured about the same duration of postrotatory nystagmus in otosclerotic patients as in normal subjects (1954), while the threshold of after-nystagmus in otosclerotic patients is raised (Hulk and Jongkees, 1948).

alkaline phosphatase in both the osteocytes and the ground substance. Abnormal accumulation of mucopolysaccharides in the otosclerotic focus was also observed. Ricci suggested that the primary cause of otosclerosis was a certain change in the ground substance. Alberti and Tarkkanen (1963) have shown that there is an increased amount of *leucine aminopeptidase and non-specific esterases* present in the otosclerotic lesions, particularly in the perivascular fibroblasts and the osteocytes.

The participation of vascular changes in the genesis of decalcification has also been proposed (Wolf and Lempert 1965). Rüedi (1964, 1969) observed abnormal vascular connections between the membranous labyrinth and the focus. These take the form of a circumscribed increase in the vascular loops and a proliferation of the epithelium of the stria. It appears that this strial proliferation probably occurs as a result of a circulatory disturbance in the region of the cochlear branch of the internal auditory artery. The circulatory disturbance is caused by vascular demands made by the actively growing otosclerotic deposit.

It has also been verified that there are microfoci between the focus and normal tissue demonstrable only under an electron microscope (Chevance et al. 1969). The endothelial cells of the capillary network of the focus were, however, found to be normal.

C. *Changes in the composition of the perilymph in association with otosclerosis*

The nature of the origin of the perilymph has not yet been clarified. The perilymph is assumed to be of an extracellular character with low potassium and high sodium concentration.

In 122 otosclerotic patients the perilymph *and the serum showed the same frequency* dispersion for the concentration of glucose, calcium, sodium and potassium. The values of maximum lacticacid dehydrogenase activity in the serum and the perilymph did not differ. The values *were much higher in the* serum and the perilymph than in the liquor. The mean phosphate concentration of the perilymph was also higher than that in the serum (Schindler et al. 1965). In 15 patients suffering from severe otosclerosis the contents of the alfa and beta globuline fractions had reduced (Chládek and Opplt 1966). The latter established further that there was a distinct relationship between the range of the protein spectrum in the perilymph and the activity of otosclerosis (1968). A correlation between the increased potassium and protein values and the preoperative hearing impairment for the bone conduction at 4 000 Hz was statistically proved by 155 otosclerotic patients (Ruedi 1965). No statistical correlation was however evident between the increased potassium and protein values and the pre- or postoperative vestibular symptoms in otosclerotic patients. Alkaline phosphatase was also found in the perilymph of otosclerotic patients. The mean value was as high as 2.3 B.E. (Bodansky Einheiten = Bodansky Units). There is no alkaline phosphatase in the perilymph of a normal ear.

D. Vertigo and electronystagmographic findings in patients suffering from otosclerosis

a. Electronystagmography (ENG) and caloric tests

Studies of vestibular changes in otosclerotic patients are remarkably less frequent than those of other otosclerotic disorders. Before the ENG-era, disturbances in the vestibular system could only be verified in extremely *few otosclerotic cases. Although 27 per cent* of 77 patients declared anamnestically that they suffered from vertigo, only five cases revealed deviations from the normal reactions in the caloric tests (Rasmussen 1949). Likewise Hulk and Jongkees (1950) were unable to verify either spontaneous or positional nystagmus on the one hand, or deviations in the caloric tests on the other hand when studying 50 patients, 30 per cent of whom declared anamnestically that they suffered from unsteadiness while walking and from fits of dizziness on stopping.

Aschan et al. (1956) were unable to *verify any nystagmus in a* clinical investigation with Frenzel's glasses on one patient who showed spontaneous nystagmus in the ENG recording. Reinecken (1960) described some electronystagmographic findings in as

In supine position
in both lateral positions and
with head hanging

The nystagmus findings were considered positive if the speed of the slow phase of the horizontal nystagmus exceeded 7°/sec.

The optokinetic nystagmus of the subjects was investigated at 30 and 60 /sec to the right and t the left alternately to exclude ertigo other than labyrinthine.

b Caloric tests

The caloric tests were performed according to Hallpike with the following exceptions The irrigation time was only 30 seconds The induced nystagmus was recorded for 70 seconds while the subject kept his eyes closed Thus reaching the culmination phase was positively secured At the 70[th] second the subject was requested to open his eyes and to fix his gaze on a fixation light which was located approximately two metres directly in front of the subject For each irrigation total amplitude and the angular locity of the slow nystagmic phase during the culmination phase were calculated The result was considered canal paresis (uni lateral hypoexcitability) when reactions before the fixation in one ear were 20 per cent weaker than those in the other ear Correspondingly the result was regarded as directional preponderance when the intensity of nystagmus with a tendency in one direction was 20 per cent greater than in the ther All the subjects whose ocular fixation index (OFI) was higher than 50 per cent were excluded because these subjects the origin of the nystagmus observed in ENG investigation might be other than labyrinthine (Demanez and Ledoux, 1970)

Silver silverchloride electrodes 7 mm in diameter were employed The tw recording electrodes were located on the skin near the temporal canthi of the lids of the two eyes, the earthed electrode was placed on the skin of the forehead The electrodes were fixed with adhesiv tape and electrode jelly was tilized to improve the contact DC differential amplifier direct ink writing (Elema mingograph) was employed Before and after every investigation the apparatus was calibrated by a ten degree movement of the eyes.

c. Rotatory tests

The rotatory tests were carried out by means of Polman s rotating chair (Polman Mod. 11 o 111) which enables linear adjustment of acceleration and deceleration speeds from 0,2 /sec² onwards. The same type of electrode and the same pattern of fixating the electrodes were used as previously An A C condenser coupled amplifier (Polman Mod MP 11) time constant 2 seconds, was utilized for the recording. All recordings were performed in darkness The subject s head was fixed tilted 30 degrees forward from the vertical.

The linearity of acceleration and deceleration of the chair was controlled by the following method All the possible acceleration and deceleration speeds employed were investigated by accelerating and decelerating the chair for exactly 30 60 and 90 seconds. After this the rotating time of the chair was measured as the mean time f 10 rotations. The speed thus obtained was the same as the theoretical speed ± 5 per cent Thus the linearity of acceleration and deceleration was confirmed.

The threshold of acceleration and deceleration was measured in the way described below The subject was accelerated for 90 seconds t a speed of 0,2 /sec² beginning to the right Then he was rotated at a constant speed for 120 seconds, after which he was decelerated t a speed of 0,2 /sec² 120 seconds after stopping the same procedure was repeated, but this time in the opposite direction This procedure was conti ued with a simultaneous 0,2 /sec² increase in the speed of acceleration and deceleration for each new stage of acceleration and deceleration until continuous nystagmus was observed

The total amplitude during the acceleration of 1 /sec² up to the final speed of 60 /sec was also reckoned. Four otosclerotic patients whose threshold of angular acceleration was higher than 1 /sec² were excluded.

The postrotatory nystagmus was measured after an abrupt stop (0,3 sec) Before the stop the speed of rotation was maintained at 60 /sec. Calculations were made of the total amplitude and the maximum frequency for a period of ten seconds. If there was a

IV Material and methods

A. Material

The material of the study consists of 60 patients (31 females and 29 males) suffering from clinical otosclerosis. The patients were aged from 18 to 64 (the mean age being 4? years)

After the investigation they were all operated on at the Otolaryngological University Clinic in Turku in 1970—1971 The diagnosis of operation was otosclerosis in all sixty cases. Tissue samples were taken from ?0 patients for histopathological diagnosis. In eighteen cases the diagnosis was confirmed as otosclerosis in two cases the sample was too small to provide sufficient material for investigation. Cases with head trauma, any neurological disorders or any previous operations on the ear were totally excluded The distribution of the material according to age and sex is shown in table 1

The group of control subjects consists of nurses assistant nurses and other workers at the clinic, numbering ?0 in all The mean age of the control group was 40 individual ages varying between 27 and 50 Cases with anamnestic head trauma anamnestic vertigo or dizziness any neurological disorders or any anamnestic diseases of the ear were excluded. All control subjects had normal hearing The distribution of the control group according to age and sex is shown in table ..

B. Methods

1 *Neuro-otological and audiological examination*

The anamnesis was made as scrupulously as possible. Special attention was paid to any occurrence of otosclerosis in the patient's family to the duration of the symptoms, to any occurrence of vertigo or tinnitus and to the presence of paracusis. The patients were also submitted to neuro-otological investigation to exclude vertigo other than labyrinthine.

Air and bone conduction audiograms were measured by the usual descending ascending technique Speech thresholds and discrimination were determined for each patient as described by Palva (195?) Loudness recruitment was measured by Fowler method A Madsen OB-60 audiometer was used The audiometer was calibrated according to ISO Recommendation R 389

? *Electronystagmographic investigation*

a Spontaneous and positional nystagmus

Any spontaneous r positional nystagmus was recorded in a dim room while the subject was lying with closed eyes

in a supine position
in both lateral positions and
with head hanging

The nystagmus findings were considered positive if the speed of the slow phase of the horizontal nystagmus exceeded 7°/sec.

The optokinetic nystagmus of the subjects was investigated at 30 and 60 /sec to the right and to the left alternately to exclude vertigo other than labyrinthine.

b Caloric tests

The caloric tests were performed according to Hallpike with the following exceptions The irrigation time was only 30 seconds. The induced nystagmus was recorded for 70 seconds while the subject kept his eyes closed Thus reaching the culmination phase was positively secured At the 70th second the subject was requested to open his eyes and to fix his gaze on a fixation light which was located approximately two metres directly in front of the subject. For each irrigation total amplitude and the angular velocity of the slow nystagmic phase during the culmination phase were calculated The result was considered canal paresis (unilateral hypoexcitability) when reactions before the fixation in one ear were 20 per cent weaker than those in the other ear Correspondingly the result was regarded as directional preponderance when the intensity of nystagmus with a tendency in one direction was 20 per cent greater than in the other All the subjects whose ocular fixation index (OFI) was higher than 50 per cent were excluded because in these subjects the origin of the nystagmus observed in ENG investigation might be other than labyrinthine (Demanez and Ledoux, 1970)

Silver silverchloride electrodes 7 mm in diameter were employed The two recording electrodes were located on the skin near the temporal canthi of the lids of the two eyes, the earthed electrode was placed on the skin of the forehead The electrodes were fixed with adhesive tape and electrode jelly was utilized to improve the contact DC differential amplifier direct ink writing (Elema mingograph) was employed Before and after every investigation the apparatus was calibrated by a ten degree movement of the eyes.

c. Rotatory tests

The rotatory tests were carried out by means of Polman's rotating chair (Polman Mod. II e III) which enables linear adjustment of acceleration and deceleration speeds from 0,2 /sec² onwards The same type of electrode and the same pattern of fixating the electrodes were used as previously An A.C. condenser coupled amplifier (Polman Mod MP 11) time constant 2 seconds, was utilized for the recording All recordings were performed in darkness The subject's head was fixed tilted 30 degrees forward from the vertical

The linearity of acceleration and deceleration of the chair was controlled by the following method All the possible acceleration and deceleration speeds employed were investigated by accelerating and decelerating the chair for exactly 30, 60 and 90 seconds. After this the rotating time of the chair was measured as the mean time for 10 rotations The speed thus obtained was the same as the theoretical speed ± 5 per cent. Thus the linearity of acceleration and deceleration was confirmed.

The threshold of acceleration and deceleration was measured in the way described below The subject was accelerated for 90 seconds at a speed of 0,2 /sec² beginning to the right. Then he was rotated at a constant speed for 120 seconds, after which he was decelerated at a speed of 0,2 /sec² 120 seconds after stopping the same procedure was repeated, but this time in the opposite direction This procedure was continued with a simultaneous 0,2 /sec² increase in the speed of acceleration and deceleration for each new stage of acceleration and deceleration until continuous nystagmus was observed

The total amplitude during the acceleration of 1 /sec² up to the final speed of 60 /sec was also reckoned. Four otosclerotic patients whose threshold of angular acceleration was higher than 1 /sec² were excluded

The postrotatory nystagmus was measured after an abrupt stop (0,3 sec) Before the stop the speed of rotation was maintained at 60 /sec. Calculations were made of the total amplitude and the maximum frequency for a period of ten seconds If there was a

divergence of more than 20 per cent between nystagmus to the right and to the left the result was regarded as directional preponderance.

The statistical significances of all measurements mentioned above were counted by Student's t test and the contingency tables were tested using the Chi square test.

V Results

A. Anamnestic data

Anamnestic data on the patients are given in tables 3 and 4. Twenty-seven of the subjects examined (45 per cent) had close relatives (mother father brother or sister) with diagnosed otosclerosis. Thirty-nine patients (65 per cent) had suffered from hearing loss or tinnitus for at least five years before treatment. Moreover 34 (57 per cent) cases complained anamnestically of brief periods of vertigo (not exceeding 30—60 seconds) during which they felt the horizon rocked and the world seemed to roll from side to side. According to many patients, these symptoms were associated with rapid movements of the head, abrupt stops or with turns. Many patients furthermore felt unsteadiness while walking in the dark or with their eyes closed. Seventeen (28 per cent) patients complained of tinnitus and paracusis was anamnestically demonstrated in 50 per cent of the patients. The main reason for resorting to medical treatment was hearing loss in 53 cases (88 per cent). Tinnitus in one or both ears was given as the main reason by 7 patients (12 per cent) who also considered tinnitus more provoking than hearing loss.

standard deviation, maximum and minimum hearing loss are given in table 6. Figure 2 presents the hearing results as an audiogram. Table 7 shows the mean hearing loss (air conduction and bone conduction) and the other values mentioned above in the better ear and in the worse ear (the ear which is to be operated on). The corresponding audiogram is shown in figure 3.

The hearing loss (air conduction) in the ear to be operated on was 48—56 dB on an average and that in the better ear approximately 37—47 dB. The bone conduction hearing values were correspondingly 10—25 dB in the worse ear and 10—20 dB in the better. The average air bone gap was approximately 35 dB in the worse ear and about 20 dB in the better ear.

C. Electronystagmographic findings

a. Control series

1—4. Positional nystagmus, caloric tests, rotatory tests and postrotatory nystagmus

Examinations with Frenzel's glasses or electronystagmography did not reveal any perceptible nystagmus.

In caloric tests two subjects showed directional preponderance as measured from maximum eye speed. One of them showed directional preponderance even as measured from total amplitude.

Reduced caloric excitability was demonstrated in one subject as measured from total amplitude. Yet no divergence was perceived in caloric excitability between the two ears when the maximum eye speed was being measured. The results are given in table 9.

The threshold of angular acceleration and deceleration in the control series are shown in table 10, which likewise presents the standard deviation and the highest and lowest thresholds of acceleration and deceleration observed in this group. When stopping abruptly from the speed of 60°/sec. the following mean summed amplitudes of the slow phase of the first postrotatory nystagmus in control series were manifested: 119° right nystagmus beating and 117° left beating. The maximum frequency for a period of ten seconds was correspondigly 18,2 nystagmus beatings to the right and 19,2 to the left.

Hypoexcitability (canal paresis)	34	56 7	33	55	25	41 7

b Clinical otosclerosis

1 Positional nystagmus

Positional nystagmus was observed with Frenzel glasses in five patients suffering from otosclerosis (0,3 per cent) The results are given in table 11 By electronystagmography the nystagmus was recorded in 20 patients (33,3 per cent) Five of these (25 per cent) revealed direction-changing (Nylen type I) fourteen (70 per cent) showed direction-determined (Nylen's type II) and one patient (5 per cent) showed irregular direction-changing (Nylen type III) nystagmus (Aschan et al 1956) These results are shown in tables 12 and 13

2 Caloric tests

In the caloric tests directional preponderance was observed in 29 patients (48,3 per cent) as measured from maximum eye speed and in 32 patients (53,3 per cent) as measured from total amplitude Directional preponderance occurred in 22 patients (36.7 per cent) when measured from maximum eye speed and total amplitude jointly In ten of these it was on the side of the better ear and in twelve cases on the side of the worse ear

Thirty four patients (56,7 per cent) revealed unilateral hypoexcitability in caloric tests as measured from maximum eye speed and 33 patients (55 per cent) as measured from total amplitude Unilateral hypoexcitability in the caloric tests was manifested in 25 patients (41 7 per cent) when measured from maximum eye speed and total amplitude jointly In twelve of these it was in the ear with better hearing and in thirteen cases in the poorer ear The results are shown in table 14

Directional preponderance was consequently observed significantly more frequently in patients suffering from otosclerosis than in control subjects ($p < 0{,}01$ when measured from maximum eye speed and $p < 0{,}001$ when measured from total amplitude) Caloric hypoexcitability was even found in otosclerotic patients to a significantly greater degree than in healthy subjects ($p < 0{,}001$ when measured from total amplitude)

3 Rotatory tests

The thresholds of angular acceleration and deceleration for patients suffering from otosclerosis are presented in table 15. To facilitate reading table 16 gives a combination of the two preceding tables presenting the mean thresholds in the two groups parallelly Table 16 also includes the standard deviation, the t-test values and any significance (p) In the control series, the threshold of acceleration to the right was 0,37 °/sec² and to the left 0,32 °/sec² The thresholds of deceleration correspondingly showed the following values 0,33°/sec² to the right and 0,37 °/sec² to the left These differences are not statistically significant

Table 15 *Patients suffering from otosclerosis The thresholds of angular acceleration and deceleration during rotatory tests (expressed in degrees/sec²) Mean standard deviation maximum and minimum values*

	Otoscl. patients	0 58	0.33		
The threshold of angular acceleration to the left	Control series	0.32	0 10	6 552	0 001
	Otoscl. patients	0 60	0 28		
The threshold of angular deceleration to the left	Control series	0.37	0 12	2.799	0 01
	Otoscl. patients	0 50	0 28		

The corresponding values of thresholds for patients suffering from otosclerosis were 0 49 /sec² to the right and 0 60 /sec² to the left during the acceleration phase. The thresholds of deceleration showed the following values 0,58 /sec² to the right and 0 50 /sec² to the left The differences are not statistically significant, either However the threshold of angular acceleration and deceleration in the control group is significantly lower than the values established in the patients suffering from otosclerosis (table 16) The threshold of angular acceleration to the right was as low as 0 37 /sec² in the control series while the prevailing value for the patients was as high as 0 49 /sec² ($p <$ 0 05) Correspondingly the thresholds of acceleration to the left gave the values 0,32 /sec² and 0 60 /sec² ($p <$ 0 001) The thresholds of deceleration to the right were parallelly 0 33 /sec² and 0,58 /sec² ($p <$ 0 001) while the values of the thresholds when decelerating to the left were 0 37 /sec² and 0,50 /sec² ($p <$ 0 01)

Table 17 shows the thresholds of angular acceleration and deceleration in the affected and in the clinically healthy ear in the seventeen patients with clinical otosclerosis in one ear only The thresholds of acceleration in the affected ear was 0 68 /sec² and in the healthy ear 0 54 /sec² The corresponding values for the deceleration thresholds were 0,56 /sec² and 0 67 /sec² These differences are however not statistically significant The thresholds in these patients are significantly higher than the corresponding values established in the control group though, ($p <$ 0 01) The joint mean threshold of acceleration in the control series (calculated from the right and the left side jointly) was 0 35 /sec² the joint mean threshold of deceleration showing precisely the same value (0,35 /sec²)

Table 18 presents a comparison between the values.

Table 19 shows the mean thresholds of angular acceleration and deceleration to the side of the more affected ear (0,56 /sec² and 0,53 /sec²) and to the side of the better ear (0,53 /sec² and 0,54 /sec²) in patients suffering from otosclerosis. There are no statistically significant differences between the two sides. The differences between the joint mean thresholds of the control subjects (0,35 /sec²) and patients suffering from otosclerosis are, however highly significant ($p <$ 0 001) The comparison is presented in table 20

The corresponding values of thresholds for patients suffering from otosclerosis were 0.49 /sec² to the right and 0.60 /sec² to the left during the acceleration phase. The thresholds of deceleration showed the following values 0,58 /sec² to the right and 0,50 /sec² to the left. The differences are not statistically significant either. However the threshold of angular acceleration and deceleration in the control group is significantly lower than the values established in the patients suffering from otosclerosis (table 16). The threshold of angular acceleration to the right was as low as 0,37 /sec² in the control series while the prevailing value for the patients was as high as 0.49 /sec² ($p < 0{,}05$). Correspondingly the thresholds of acceleration to the left gave the values 0.32 /sec² and 0.60 /sec² ($p < 0.001$). The thresholds of deceleration to the right were parallelly 0,33 /sec² and 0.58 /sec² ($p < 0.001$) while the values of the thresholds when decelerating to the left were 0.37 /sec² and 0.50 /sec² ($p < 0.01$).

Table 17 shows the thresholds of angular acceleration and deceleration in the affected and in the clinically healthy ear in the seventeen patients with clinical otosclerosis in one ear only. The thresholds of acceleration in the affected ear was 0.68 /sec² and in the healthy ear 0.54 /sec. The corresponding values for the deceleration thresholds were 0.56 /sec and 0.67 /sec. These differences are however not statistically significant. The thresholds in these patients are significantly higher than the corresponding values established in the control group though, ($p < 0.01$). The joint mean threshold of acceleration in the control series (calculated from the right and the left side jointly) was 0,35 /sec² the joint mean threshold of deceleration showing precisely the same value (0.35 /sec²).

Table 18 presents a comparison between the values.

Table 19 shows the mean thresholds of angular acceleration and deceleration to the side of the more affected ear (0,56 /sec² and 0,53 /sec²) and to the side of the better ear (0.53 /sec² and 0,54 /sec²) in patients suffering from otosclerosis. There are no statistically significant differences between the two sides. The differences between the joint mean thresholds of the control subjects (0,35 /sec²) and patients suffering from otosclerosis are, however highly significant ($p < 0.001$). The comparison is presented in table 20.

6 000 Hz in air conduction ($p < 0.01$). The results are shown in table 25.

Hypoexcitability on one side in the caloric tests was manifested in 25 patients. The hearing of this side was not statistically significantly lower than the hearing of the opposite side.

The occurrence of recruitment in proportion to nystagmus findings is shown in table 26. Positional nystagmus was discovered in all patients with recruitment. The divergence is statistically highly significant ($p < 0.001$). The hearing results of these patients with recruitment are shown in table 27 and figure 4.

Table 28 correspondingly shows the occurrence of subjective tinnitus in proportion to nystagmus findings. Positional nystagmus was found to be of a significantly higher degree in the patients complaining of subjective tinnitus than in the other otosclerotic patients ($p < 0.01$). On the other hand patients who had vertigo or paracusis anamnestically did not show significantly more perceptible positional nystagmus than those lacking the symptoms mentioned. There are no statistically significant differences between the

hearing of these patients with anamnestic tinnitus and with no anamnestic tinnitus. The hearing results are presented in table 29 and figure 5.

Twenty four patients had bone conduction values worse than 20 db (Mean of 250, 500, 1 000, 2 000, 4 000 Hz). Ten of these had also positional nystagmus in ENG investigation. The otosclerotic patients with sensorineural hearing loss had more vestibular disturbances than others. However this difference is not statistically significant.

VI Discussion

In this investigation 34 patients (57 per cent) anamnestically complained of vertigo and unsteadiness while walking which is more than in any previous investigations. Only fourteen of these 34 patients showed nystagmus in ENG-investigation, however Nystagmus in ENG was observed in six further patients (who anamnestically revealed no vertigo or unsteadiness) Consequently ENG investigation does not always indicate nystagmus, despite anamnestic subjective vertigo Symptoms pointing to vestibular disturbances have been observed in otosclerotic patients by Rasmussen (1949) Hulk and Jongkees (1950) Aschan Bergstedt and Stahle (1956) Reinecken (1960) Fisch (1965) and Rüedi et al. (1965) Nevertheless comparatively sparse investigations on the pre-operative state have been published so far

Reinecken, for instance, has demonstrated positional nystagmus in 25 per cent and Fisch in 28 8 per cent of such patients Meurman et al. found positional nystagmus, directional preponderance or hypoexcitability in the caloric tests in 35.5 per cent of patients. *In this investigation positional nystagmus was verified in 20 patients (33,3 per cent)* which is approximately the same amount as in the previous investigations.

No positional nystagmus was demonstrated in the control series, but directional preponderance (a difference exceeding 20 per cent between the nystagmus values to the right and to the left) in the caloric tests was present in two subjects when measured from the maximum eye speed and in one when measured from total amplitude As calculated before, the patients suffering from otosclerosis revealed correspondingly directional preponderance in 29 and 32 cases These divergences between the control series and the patients suffering from otosclerosis were statistically significant ($p < 0.01$ and $p < 0.001$)

Unilateral hypoexcitability in the caloric tests (a difference exceeding 20 per cent between the two sides) was revealed in 34 patients (56.7 per cent) when measured from maximum eye speed and in 33 patients (55 per cent) when measured from summed amplitude The control series, on the other hand showed unilateral hypoexcitability in one subject only when measured from summed amplitude *The difference between the control group and the group of patients is highly significant ($p < 0,001$)*

The mean summed amplitudes of the slow phase of the nystagmus in the caloric tests did not statistically differ in patients suffering from otosclerosis and in control series.

Anamnestic tinnitus was demonstrated in 17 patients, and 11 of these (65 per cent) showed positional nystagmus in the ENG-investigation. These seventeen patients thus showed significantly more commonly nystagmus than the patients with no anamnestic tinnitus ($p < 0.01$) This observation has not been described in the literature.

Conductive hearing loss in otosclerosis is due to the fixation of the stapes in the oval window region Sensorineural hearing loss also occurs in association with otosclerosis. According to Shambaugh (1959) the cochlear damage is probably due to toxic secretions entering the endolymph. Active otosclerotic foci extending to the endosteum produce larger quantities of these substances injurious to the organ of Corti than does an inactive focus Fisch (1965) suggested that an otosclerotic vascular change or a biochemical change in the inner ear fluids might be the reason for cochlear and vestibular disturbances because the terminal fibres of nervus utricularis and nervi ampullares run freely in the perilymphatic space and can thus come into direct contact with the perilymph in association with biochemical changes caused by otosclerosis When examining the perilymph of otosclerotic patients Chládek and Opplt (1966) have described reduced alfa and beta globuline fraction in these patients Further Chládek and Opplt

(1968) established that there was a relationship between the range of the protein spectrum in the perilymph and the otosclerosis activity Rüedi et al. (1965) observed higher calcium and protein values than normal in the perilymph of otosclerotic patients and also verified alkaline phosphatase, which does not normally exist in the human perilymph However it appears that otosclerosis should not be a common cause of sensorineural hearing loss (Gross 1968) Schuknecht (1971) suggests that in general, otosclerosis probably has no effect on the cochlea of most patients There are however severe cases of otosclerosis in which much of the otocapsule is involved, possibly with some lamellar new bone ingrowth where severe degenerative lesion brought about by otosclerosis definitely prevails. The patients with descending audiometric pattern, which most commonly appears in association with otosclerosis, would probably have had the same pattern even without otosclerosis, but on the other hand there is, according to Schuknecht, no pure cochlear otosclerosis without any stapes fixation The average hearing loss of air conduction in this investigation was 50—60 dB in the more affected ear The average hearing loss of bone conduction from 250 to 1 000 Hz was about 10–15 dB and from 2 000 to 4 000 Hz 20—25 dB The sensorineural hearing loss was thus proved to be more pronounced for high tone The control series did not show any pronounced hearing loss of the above kind *The patients with objective vestibular disturban es also et al d mor perspicuous sensori neural hearing loss than the ther This d fferenc* which is i agreement w th Fisch 1965) *is statistically sign ficant at 4 000 H in bon conduction (table 25)*

The recruitment phenomenon was previously assumed to be associated with peripheral, perceptive hearing loss only It has been shown, however that recruitment also occurs in association w th pure conductive hearing loss, as w th otosclerosis, for instance (Karja 1970) The phenomenon is presumed to be caused by the immobilization of the stapes nd ■ probably a result of an altered stimulation pattern on the basilar membrane brought about by hydrodynamic changes in the cochlea (Anderson and Barr 1966)

Recruitment was found in seven patients (12 per cent) in this investigation, and all these patients showed objective vestibular disturbances as well.

In earlier investigations the thresholds of angular acceleration in normal subjects vary as shown by calculations made by Groen and Jongkees 0,5 /sec² (1948) Hilding 0 75—1,0°/sec² (1953) Montandon et al 0,8 / sec² (1955) and Decher 0 4 /sec² (1965) These variations are caused at least partially by the different methods and apparata employed In this investigation the acceleration was begun at the rate of 0,2 /sec² and after an acceleration of 90 seconds the rotation was kept constant for 120 seconds before the deceleration phase The rates of acceleration and deceleration were always identical and they were heightened gradually by 0,2 / sec² at a time until the threshold was reached for both sides Between every rotation there was a pause of 120 seconds for recovery In this investigation the thresholds of acceleration in the control series were 0,37 /sec² to the right and 0,32 /sec² to the left, and correspondingly the thresholds of deceleration were 0,33 /sec² to the right and 0,37 /sec² to the left Thus the threshold of acceleration to the right and the threshold of deceleration to the left were about identical and vice versa The differences between the two sides are slight and have no statistical significance. The thresholds of control subjects are a little lower than in the previous investigations.

Th th eshold of ac le ation was 0 49°/ sec² to the right and 0,60/sec² to the left The th esholds f d cleratio we e 0,58 / c² t the right and 0.50°/ c² to the left Th differences in th esholds between the two sides ar not statistically significant but th thresholds f otosclerot patients are statist cally significantly higher than those of the ontrol serie (table 16)

In the 17 patients who had unilateral tosclerosis, the threshold of acceleration to the side of the affected ear was 0,68 /sec² and that to the side of the clinically healthy ear 0,54 /sec² The thresholds of deceleration are almost identical 0,56°/sec² and 0,67 / sec² These differences are not statistically significant. The thresholds of acceleration show statistically significant differences between the control group and otosclerotic patients both for the more affected ear and for the clinically healthy ear (p < 0,01)

The thresholds of acceleration for the more affected ear and for the better ear in patients suffering from otosclerosis (60 patients) are approximately identical (0,56 °/sec² and 0,53 °/sec²). These two thresholds are, however, statistically very significantly higher than the thresholds of the control series in which the corresponding values are 0,35 °/sec² and 0,35 °/sec² ($p < 0.001$).

When employing the rate of 1 °/sec² which is about 0.5 °/sec² higher than the average threshold during the acceleration phase there were no statistically significant differences in the summed amplitude of the slow phase of perrotatory nystagmus in the course of acceleration from zero to 60 °/sec between otosclerotic patients and the control series (table 21). Thus the elevated thresholds of angular acceleration and deceleration in otosclerotic patients might be presumed to be inflicted by changes in the perilymph of the labyrinth in association with otosclerosis.

Previous investigations have established that the first postrotatory nystagmus in otosclerotic patients is of shorter duration than in normal subjects (Rasmussen 1949, Hulk and Jongkees 1950). *In this investigation there was no statistically significant difference in the summed amplitude of the slow phase of the first postrotatory nystagmus between otosclerotic patients and the control series. No difference was demonstrated in the maximum frequencies of postrotatory nystagmus during the ten seconds control period either.*

Thus it can be concluded that the most commonly prevailing vestibular disturbances in patients suffering from otosclerosis are firstly caloric hypoexcitability and a heightened threshold of angular acceleration and deceleration, secondly directional preponderance and thirdly positional nystagmus in this order of frequency. All these abnormalities, as well as the sensorineural hearing loss, may be caused by the same factor connected with the otosclerotic focus in the labyrinthine capsule.

VII Summary

The aim of this study was to investigate the preoperative vestibular disturbances in patients suffering from otosclerosis. The material consisted of 60 patients suffering from otosclerosis and 20 control subjects. All patients and control subjects with any previous ear operation or head trauma were excluded. In addition to pure tone tests, speech audiometric tests and if possible loudness balance tests according to Fowler were also performed. The occurrence of spontaneous and positional nystagmus was investigated with ENG. The caloric tests were carried out according to Hallpike and in the rotatory tests Poltman's rotatory chair was utilized (Mod. II e III).

In the ENG investigation 20 patients (33,3 per cent) revealed positional nystagmus. In five of them the nystagmus was direction-changing (Nylén's type I), in fourteen the nystagmus was found to be direction-determined (Nylén's type II) and in one patient the nystagmus type was irregular direction-changing (Nylén's type III).

In the caloric tests directional preponderance was verified in 29 cases (48 per cent) when measured from the maximum eye speed and in 32 cases (53 per cent) when measured from the summed amplitude of the slow phase of nystagmus. Twenty-two patients (37 per cent) showed directional preponderance when calculated by the two methods jointly.

Caloric excitability was found to be reduced in 34 patients (57 per cent) (a difference exceeding 20 per cent between the two sides) when measured from the maximum eye speed and in 33 cases (55 per cent) when measured from the summed amplitude of the slow phase of nystagmus. Twenty-five patients (42 per cent) revealed a lower caloric excitability when calculated by the two methods jointly.

Statistically significantly there are more numerous cases of directional preponderance and lowered caloric excitability in otosclerotic patients than in normal control subjects.

Patients with objective vestibular disturbances showed greater hearing losses at high frequencies than the others. The difference was statistically significant at 4 000 Hz in bone conduction and at 4 000 and 6 000 Hz in air conduction.

The mean thresholds of angular acceleration in otosclerotic patients were 0,49 $/sec^2$ to the right and 0,60 $/sec^2$ to the left. The corresponding values for deceleration thresholds were 0,58 $/sec^2$ and 0,50 $/sec^2$. These values are all statistically significantly higher than in the control group.

The mean threshold of angular acceleration in this group was to the right 0,37 $/sec^2$ and to the left 0,32 $/sec^2$. The values for deceleration were correspondingly 0,33 $/sec^2$ and 0,37 $/sec^2$.

Patients suffering from otosclerosis and the control series revealed no statistically significant difference when accelerating from zero to 60 /sec at a rate of 1 $/sec^2$ as measured from the summed amplitude of the slow phase of perrotatory nystagmus.

This investigation tends to demonstrate that patients suffering from otosclerosis very frequently show vestibular disturbances. The objective disturbances manifested were firstly caloric hypoexcitability and elevated thresholds of angular acceleration and deceleration, secondly directional preponderance and, thirdly positional nystagmus.

VIII Acknowledgements

My chief and teacher in oto-laryngology Professor Otto H. Meurman M.D Head of the Otolaryngological University Clinic, Turku suggested this subject to me. During the course of this study he has given me good advice and showed unfailing interest for my work I wish to express my deep graditude to him.

I also wish to thank Dr Eero Aantaa M D whose guidance and instructions have been of great help to me throughout my studies.

I also thank Docent Juhani Kärjä M.D for his valuable criticism of the manuscript

I am grateful to Mr Pertti Koskinen, M.Sc. for statistical analysis of the results. Mrs. Leila Rinne for her assistance in examination of the patients, Mr Erkki Makkonen. Mag Phil for translating this thesis into English Mrs. Diana Tullberg B A. for checking the English language and Mrs. Raija Koskinen for typing the manuscript

My thanks are due to the staff of the Otolaryngological Clinic for their co-operation and help during the study

Last but not least I wish to thank my wife for her support during the course of this investigation.

1 INTRODUCTION AND PURPOSE OF THE STUDY

Chronic otitis media has been one of the most important subjects of otologic studies for over a hundred years. Research on middle ear histopathology was particularly lively late in the 19th and in the early decades of the 20th century the main subjects being the process of pneumatization and the etiology of cholesteatoma. Wittmaack published in 1918 his classical theory of pneumatization while von Troltsch (1868) Wendt (1873), Habermann (1888), Bezold (1888 1890), Politzer (1901), Wingrave (1910) Manasse (1917), Lange (1925) Nager (1925) Döderlein (1930) McKenzie (1931) and Albrecht (1931) were among the authors who discussed theories concerning the genesis of cholesteatoma.

Since World War II the use of the operating microscope has much increased the interest in ear surgery and in the changes thus observed. This, and new histological research methods, gave new impetus to the study of the histopathology of the middle ear Structural details of the middle ear mucosa were further clarified in the 1960s by the studies of Bendek (1963), Friedmann (1963) and Sadé (1965 1966 a) in particular Sadé (1965 1966 a) showed that the middle ear had a true mucosa with its secreting components and epithelial lining of a partly respiratory type During the last five years numerous histologic and cytologic studies based on light and electron microscopy as well as biochemical and microbiological studies of middle ear processes, have given us new and more extensive views on the nature of the tympanic mucosa.

One interesting recent finding was that specimens of middle ear mucosa, taken in connection with chronic ear surgery showed stratified squamous epithelium without cholesteatoma (T Palva et al., 1968) Although the removal of tympanic mucosa in these cases was not total, there was not a single case of cholesteatoma developing during the follow-up period of 4—5 years. The authors felt that two types of squamous epithelium exist. the "resting" hyperkeratotic, and that with slight or no keratinization with the general function of covering the epithelial defects of the tympanic mucosa. Only the hyperkeratotic would be capable of forming cholesteatoma. The removal of the small amount of keratin possibly connected with the non-hyperkeratotic type might be explained by horizontal epithelial migration (Litton, 1968), if a connection between the squamous epithelium and the ear canal could be shown.

The purpose of the present study was to examine systematically with the aid of serial sections, the type and characteristics of the epithelium in the chronically infected middle ear Special attention is devoted to the type of any squamous epithelium, its capacity for keratin formation, and its relationship to other epithelium. These findings will be compared with the tympanic pathology and related especially to the tympanic membrane pathology and to the epithelium of the perforation margins. The genesis of tympanic squamous epithelium is investigated, and an attempt is made to further elucidate the problem of epidermosis.

ciliated cylinder epithelium both in the tube and, in addition to flat single-layer epithelium, to a varying extent in the middle ear especially in its medial and lateral walls. No glands were found in the tympanum. They considered the tympanum a wide transitional region in which the entodermal respiratory epithelium of the tubal side changed into mesodermal pseudoendothelium. The same view of the embryonal development of the middle ear space was advocated by Marowitz & Porubsky (1971) who made their studies on rats.

Bendek (1963) on a material of ten otosclerotic ears, found secretory epithelium with glandular structures in three mucosal biopsies taken from the area of the fossa ovalis. Thus suggested that secretory epithelium was normally present on middle ear mucosa. Sadé (1965 1966 a) showed that the middle ear lining is a true mucosa containing secreting cells and glands (secretion) and covered very largely by ciliated epithelium (transmission). According to Sadé (1966 a) the ciliated epithelium extended from tube to tympanum in the form of tracts which lined the anterior tympanum, the hypotympanum and, to a lesser extent, the promontory and the anterior epitympanum. The cilia, on the whole, covered one to two anteroinferior thirds of the middle ear mucosa. In addition to pseudostratified columnar epithelium, cilia were borne e.g. on the promontory by cuboidal and even flat epithelial cells. Ten per cent of his autopsy material of 80 normal middle ears showed goblet cells in the neighbourhood of the orifice of the Eustachian tube whence they extended to the inferior tract, glands were seen beneath the ciliated epithelium in most ears.

Hentzer (1970) found that the ciliated epithelium in the middle ear region covered an even wider area than Sadé had claimed. He observed ciliated epithelium also in the area of the posterior tympanum, epitympanum, facial prominence and often even the mastoid air cells. Furthermore, unlike Sadé (1966a) and Buch (1967), he noted high, and even pseudostratified ciliated epithelium on some areas of the tympanic surface of ear drum, however not in the area of the flat epithelium lining the pars flaccida (Hentzer 1969). Hentzer (1970) also reported gland like structures not only around the orifice of the Eustachian tube but also in the region of the promontory.

Lim et al (1967) and Hussl & Lim (1969 a) studied with electron microscopy and Lim (1970) also autoradiographically the secretory structure and nature of the cells of the tympanic bulla in the guinea pig. Kawabata & Paparella (1969) were the first to describe the normal ultrastructure of the epithelium of human promontory the promontory was lined by columnar or cuboidal, ciliated or non-ciliated cells, under which basal cells were visible on the basement membrane (= basal lamina). They found no goblet cells. Hussl & Lim (1969 b) and Lim & Hussl (1969) found that the respiratory epithelium of the human Eustachian tube became flattened in the tympanum until it was simple flat epithelium, the area of the respiratory epithelium approximately corresponding to the maximal extension reported by Sadé (1966 a). Additionally they saw in some places ciliated cells on the inner surface of the ear drum. The secretory cell types were goblet cells (especially in the neighbourhood of the tubal orifice) and intermediate cells (more tympanally in the area of the columnar cuboidal and also flat ciliated cells) which, according to the classification by Shackleford & Klapper (1962) belong to the seromucous and serous groups, respectively.

2.2. MIDDLE EAR EPITHELIUM AND INFLAMMATION

According to Wittmaack (1918), the ciliated epithelium spread from the Eustachian tube to the tympanum only as a result of inflammation, and sometimes even extended to the air cell system. At the same time the

2 REVIEW OF THE LITERATURE

2.1 NORMAL MIDDLE EAR EPITHELIUM

According to Politzer (1878) and Preysing (1904) the middle ear was lined by ciliated epithelium over large areas that even extended to the epitympanum Preysing found *no glands* on the tympanic mucosa However von Tröltsch (1861) and Krause (1876) had already described glands in the middle ear mucosa, and the finding had been confirmed e g by Politzer (1878) and Goerke (1902 1905)

Wittmaack (1918) found ciliated epithelium only at the orifice of the Eustachian tube and over a small area of the floor of the anterior tympanum Otherwise there was simple cuboidal epithelium, with flat endothelium like areas He saw no glands in the normal tympanum Wittmaack s (1918) idea of one normal type of mucous membrane and of three pathological mucosal constitutions, was supported e.g by Steurer (1926) Alexander (1927) on the other hand asserted that all of Wittmaack s four mucosal types could be present in the same normal middle ear and the presence of ciliated epithelium in the antrum on the surface of the hyperplastic type of mucosa was only another sign of normal variation Meyer (1931) described in the tympanum all epithelial types from endothelium to the ciliated columnar epithelium producing mucus The thickness of the submucosa varied accordingly flat epithelium corresponding to thin submucosa. He was of the opinion that epithelium held the dominating role and that the submucosa (and the pneumatization of the mastoid process) were determined by the epithelial potency

According to Doderlein (1920) the ectodermal tympanal epithelium was low and cuboidal excepting the *ciliated columnar epithelium* of the tubal region Stewart (1928) shared Krainz s (1924) opinion that tympanic epithelium was of entodermal pharyngotubal origin flattening peripherally with cilia ending *in the anterior tympanum* close to the tube.

Up to the 1960s middle ear epithelium was generally believed to be low cuboidal non-ciliated unstratified and/or even endothelium like (Beck 1926 Rüedi 1937 1940 Lierle & Potter 1941 Friedmann 1955 b 1956) Only in the neighbourhood of the orifice of the Eustachian tube was it higher possibly stratifield and/or ciliated (Semenov 1936 Polvogt & Babb 1940 Maximov & Bloom 1942 Friedmann 1963) Ojala (1950) concurred with the idea of flat tympanal epithelium but showed that in pouch formations on top of a thicker subepithelial tissue layer and in the lateral wall of the hypotympanic recess, the epithelium was higher cuboidal or low columnar None of these authors found mucus secreting cells or glandular structures in the normal middle ear

In contrast to Hammar s (1902) generally accepted view that the middle ear lining was of entodermal origin Schwarzbart (1958 1959) asserted that the entodermal mucosa extended only to the isthmus of the Eustachian tube and that the bony tube (protympanum) as well as other middle ear spaces were lined with unciliated mesothelium He believed that the glandular structures were accordingly confined to the region of the cartilaginous tube (*cf* Tos, 1970) Buch & Jorgensen (1964) in their material of 135 ears of prematures in the 6th to 9th foetal month, found stratified

ciliated cylinder epithelium both in the tube and, in addition to flat single-layer epithelium, to a varying extent in the middle ear especially in its medial and lateral walls. No glands were found in the tympanum. They considered the tympanum a wide transitional region in which the entodermal respiratory epithelium of the tubal side changed into mesodermal pseudoendothelium. The same view of the embryonal development of the middle ear space was advocated by Marowitz & Porubsky (1971) who made their studies on rats.

Bendek (1963), on a material of ten otosclerotic ears, found secretory epithelium with glandular structures in three mucosal biopsies taken from the area of the fossa ovalis. This suggested that secretory epithelium was normally present on middle ear mucosa. Sadé (1965, 1966 a) showed that the middle ear lining is a true mucosa containing secreting cells and glands (secretion) and covered very largely by ciliated epithelium (transmission). According to Sadé (1966 a) the ciliated epithelium extended from tube to tympanum in the form of tracts which lined the anterior tympanum, the hypotympanum and, to a lesser extent, the promontory and the anterior epitympanum. The cilia, on the whole, covered one to two anteroinferior thirds of the middle ear mucosa. In addition to pseudostratified columnar epithelium, cilia were borne *e.g. on the promontory* by cuboidal and even flat epithelial cells. Ten per cent of his autopsy material of 80 normal middle ears showed goblet cells in the neighbourhood of the orifice of the Eustachian tube, whence they extended to the *inferior* tract. glands were seen beneath the ciliated epithelium in most ears.

Hentzer (1970) found that the ciliated epithelium in the middle ear region covered an even wider area than Sadé had claimed. He observed ciliated epithelium also in the area of the posterior tympanum, epitympanum, facial prominence and often even the mastoid air cells. Furthermore, unlike Sadé (1966a) and Buch (1967), he noted high, and even pseudostratified ciliated epithelium on some areas of the tympanic surface of ear drum, however not in the area of the flat epithelium lining the pars flaccida (Hentzer 1969). Hentzer (1970) also reported gland-like structures not only around the orifice of the Eustachian tube but also in the region of the promontory.

Lim et al. (1967) and Hussl & Lim (1969 a) studied with electron microscopy and Lim (1970) also autoradiographically the secretory structure and nature of the cells of the tympanic bulla in the guinea pig. Kawabata & Paparella (1969) were the first to describe the normal ultrastructure of the epithelium of human promontory: the promontory was lined by columnar or cuboidal, ciliated or non-ciliated cells, under which basal cells were visible on the basement membrane (= basal lamina). They found no goblet cells. Hussl & Lim (1969 b) and Lim & Hussl (1969) found that the respiratory epithelium of the human Eustachian tube became flattened in the tympanum until *it was simple* flat epithelium, the area of the respiratory epithelium approximately corresponding to the maximal extension *reported by Sadé* (1966 a). Additionally they saw *in* some places ciliated cells on the inner surface of the ear drum. The secretory cell types were goblet cells (especially in the neighbourhood of the tubal orifice) and intermediate cells (more tympanally in the area of the columnar cuboidal and also flat ciliated cells) which, according to the classification by Shackleford & Klapper (1962), belong to the seromucous and serous groups, respectively.

2.2. MIDDLE EAR EPITHELIUM AND INFLAMMATION

According to Wittmaack (1918), the ciliated epithelium spread from the Eustachian tube to the tympanum only as a result of inflammation, and sometimes even extended to the air cell system. At the same time the

2 REVIEW OF THE LITERATURE

2 1 NORMAL MIDDLE EAR EPI THELIUM

According to Politzer (1878) and Preysing (1904) the middle ear was lined by ciliated epithelium over large areas that even ex tended to the epitympanum Preysing found no glands on the tympanic mucosa *However* von Tröltsch (1861) and Krause (1876) had already described glands in the middle ear mucosa, and the finding had been confirmed e.g by Politzer (1878) and Goerke (1902 1905)

Wittmaack (1918) found ciliated epithelium only at the orifice of the Eustachian tube and over a small area of the floor of the anterior tympanum Otherwise there was simple cuboidal epithelium with flat endothelium-like areas. He saw no glands in the normal tympanum Wittmaack s (1918) idea of one normal type of mucous membrane and of three pathological mucosal constitu tions, was supported e g by Steurer (1926) Alexander (1927) on the other hand asserted that all of Wittmaack s four mucosal types could be present in the same normal middle ear and the presence of ciliated epithelium in the antrum on the surface of the hyper plastic type of mucosa was only another sign of normal variation. Meyer (1931) described *in the tympanum all epithelial types from* endothelium to the ciliated columnar epi thelium producing mucus The thickness of the submucosa varied accordingly flat epi thelium corresponding to thin submucosa He was of the opinion that epithelium held the dominating role and that the submucosa (and the pneumatization of the mastoid process) were determined by the epithelial "potency"

According to Döderlein (1920) the ecto-dermal tympanal epithelium was low and cuboidal excepting the ciliated columnar epi thelium of the tubal region. Stewart (1928) shared Krainz s (1924) opinion that tympanic epithelium was of entodermal pharyngotubal origin flattening peripherally with cilia ending in the anterior tympanum close to *the tube*

Up to the 1960s middle ear epithelium was generally believed to be low cuboidal non-ciliated unstratified and/or even endothelium like (Beck 1926 Rüedi 1937 1940 Lierle & Potter 1941 *Friedmann 1955 b* 1956) Only in the neighbourhood of the orifice of the Eustachian tube was it higher possibly stratifield and/or ciliated (Semenov 1936 Polvogt & Babb 1940 Maximov & Bloom 1942 Friedmann 1963) Ojala (1950) concurred with the idea of flat tympanal epithelium but showed that in pouch forma tions on top of a thicker subepithelial tissue layer and in the lateral wall of the hypotympanic recess, the epithelium was higher cuboidal or low columnar None of these authors found mucus secreting cells or glan *dular structures in the normal middle ear*

In contrast to Hammar s (1902) generally accepted view that the middle ear lining was of entodermal origin Schwarzbart (1958 1959) asserted that the entodermal mucosa extended only to the isthmus of the Eustachian tube and that the bony tube (protympanum) as well as other middle ear spaces were lined with unciliated mesothelium He believed that the glandular structures were accordingly confined to the region of the cartilaginous tube (cf Tos, 1970) Buch & Jorgensen (1964) in their *material of 135 ears of prematures* in the 6th to 9th foetal month found stratified

be an abrupt transition from one type of epithelium to the other and in some cases Sadé found simultaneously mucus forming and keratin-forming cells even in the same population of epithelial cells. He thought that the germinal cells of the epithelium possessed a capacity of differentiation into various directions, the results of which depended on local microenvironmental inductors.

In enzymologic studies these two types of squamous epithelium (T Palva et al., 1970 a) did not show remarkable qualitative differences, although in the cholesteatomatous type the epithelial enzyme activity usually was more pronounced. Only non-specific esterase behaved reversely whereas large subepithelial cholinesterase accumulations were seen in the active cholesteatoma of children (T Palva et al., 1971). Additional enzymological elucidation of squamous epithelium and the process of cholesteatoma has been sought e.g by Walsh (1953), Harris (1962), Paparella & Dito (1964) Jarrett & Spearman (1967) Maeda et al. (1967), Abramson (1969) T Palva et al (1970 b), Paparella et al (1970) Abramson & Gross (1971) and T Palva et al. (in press). So far however no enzymological explanation has been found for the epithelial changes in connection with middle ear inflammation. The most remarkable enzymologic finding to date is perhaps that by Abramson (1969) and Abramson & Gross (1971), viz. the pronounced collagenase activity of the cholesteatoma membrane (epithelium plus mesenchyma), which confirms the opinion (Lautenschlager 1927 McKenzie, 1931 Walsh, 1951 1953 Harris, 1962) that the cholesteatoma has a capacity for lytic expansion

2 3 CHOLESTEATOMA (EPIDERMOSIS) AND ITS ETIOLOGY

Cholesteatoma, or epidermosis (Tumarkin, 1958 1961) refers to the expansive process formed by the hyperkeratotic squamous epithelium and the underlying connective tissue. Despite assiduous research and numerous theories, the etiology of cholesteatoma is still an unresolved question. Full unanimity has not even been reached as to whether cholesteatoma is the cause or result of an inflammation (see McGuckin, 1962)

2.3 1 *The epidermoid theory (congenital cell inclusions)*

Cholesteatoma has been ascribed by many to congenital epithelial cell inclusions in the areas concerned (e.g. Körner 1899 McKenzie, 1931 Teed, 1936 Diamant, 1937 1948, 1952 1953). This theory has today been practically replaced by the assumption of an acquired etiology Primary congenital cholesteatoma does occur but only rarely in the middle ear spaces (Eggston & Wolff 1947) Case reports have been published e.g. by Lucae (1873) Kuhn (1891), Schwartze (1896) Erdheim (1905) Grove (1929), Lindsay (1934), M D Friedman & Quittner (1938), Holmes (1938), Cawthorne & Griffith (1961), Cawthorne (1963) Derlacki & Clemis (1965) Derlacki, Harrison & Clemis (1968) and Kärja & Laine (1970).

2.3.2. *The traumatic theory*

Through surgical or other trauma, epidermal material may be immigrated or implanted into middle ear spaces (e.g. Thulin, 1947 Nilsson, 1948 Kelemen, 1950 Escher 1954 Schröer 1958; Beickert, 1958 Seiferth, 1961) Traumatic etiology is generally accepted, although it explains only a fraction of the cases of cholesteatoma.

2.3.3 *The metaplastic theory*

2.3.3 1 Suppuration

According to Wendt (1873) chronic inflammation could cause squamous metaplasia of the middle ear epithelium, leading even

epithelial cells to a varying extent were transformed into goblet cells and gland like formations were also seen. In acute and chronic infection according to Wittmaack, *the extent and degree of these epithelial* changes, and the tympanal histopathology in general varied according to the type of in fection Döderlein (1920) found that in in flammation epithelial cells became oedematous and higher but the ciliated epithelium was always confined to the neighbourhood of the tubal orifice. He also noted cysts and as a result of an organization process, pseudocysts in the mucosa No true glands were seen even in a pathological tympanum Beck (1926) and Singer (1933) considered that tympanic epithelium may start secreting mucus in inflammation According to Ojala (1950) trophic stimulus resulting from in flammation produces hypertrophy of tym panic epithelium and the flat epithelium changes into ciliated columnar epithelium. Inflammation can also sometimes cause the epithelium to proliferate and produce gland like formations, in addition to the simpler secretory function

Friedmann (1955 a, b) produced an arti ficial infection in the tympanic bulla of the guinea pig and found that normal flat endothelium like epithelium was reverted to columnar epithelium of the respiratory type even containing goblet cells and gland like structures, within no more than a fortnight. In human material similar epithelial changes were noted *(Friedmann, 1956 T Palva* et al., 1964) in the mucosa of biopsies taken in connection with mastoidectomy Senturia et al (1962) cauterized the Eustachian tube in dogs and found, in about six months, glands lined by respiratory (columnar ciliated) epi thelium The glands were still noticeable after one year (Carr Ahlvin & Senturia 1967) Senturia et al (1962) observed no metaplasia to squamous epithelium and *Senturia (1963)* assumed that whatever tympanic squamous epithelium there was had immigrated

Zechner (1965 1966) and Zechner et al. (1968) found epithelial hyperplasia and meta plasia in chronic middle ear inflammation The metaplasia was either respiratory or squamous epithelial metaplasia, and both types of transformation could be seen vary ingly in the same middle ear Metaplastic squamous epithelium failed to keratinize and could be located side-by-side with columnar epithelium without any cellular or connective tissue reaction, whereas immigrating kera tinizing squamous epithelium pushed the middle ear epithelium forward, growing un derneath or sometimes over it. Zechner (1965 *1966)* also mentioned the mucosal gland like structures retention cysts and in the area of squamous epithelium intraepithelial cysts.

According to Sadé (1966 b) the middle ear mucosa in secretory otitis reacts by means of hyperplastic transformation and e.g hy peractive mucous glands are formed. Similar secretory hyperplasia was seen by Sadé & Weinberg (1967 1969) in specimens taken from chronic middle ear processes

In the study of T Palva et al (1968) referred to in the Introduction the authors assumed that, in the chronically infected tympanum two types of squamous epi thelium may appear different in clinical behaviour but except for the amount of keratin indistinguishable in histological structure The main function of non-cholesteatomatous squamous epithelium would be to line the denuded middle ear surfaces. *The resting squamous* epithelium on the other hand is hyperkeratotic and cholestea toma forming

In 60 of a total of 100 biopsies taken from chronically infected middle ear cleft mucosa, Sadé & Weinberg (1969) also found squamous epithelial metaplasia" which in 42 cases *was keratinizing Sadé (1971)* agreed that the squamous epithelium in chronic otitis was either a type that keratinized poorly or one that was hyperkeratotic, cholesteatomatous. *The same ear* could also show a change into mucus producing cells. There could

be an abrupt transition from one type of epithelium to the other and in some cases Sadé found simultaneously mucus forming and keratin-forming cells even in the same population of epithelial cells. He thought that the germinal cells of the epithelium possessed a capacity of differentiation into various directions, the results of which depended on local microenvironmental inductors.

In enzymologic studies these two types of squamous epithelium (T Palva et al., 1970 a) did not show remarkable qualitative differences, although in the cholesteatomatous type the epithelial enzyme activity usually was more pronounced. Only non-specific esterase behaved reversely whereas large subepithelial cholinesterase accumulations were seen in the active cholesteatoma of children (T Palva et al., 1971) Additional enzymological elucidation of squamous epithelium and the process of cholesteatoma has been sought e.g. by Walsh (1953), Harris (1962), Paparella & Dito (1964), Jarrett & Spearman (1967) Maeda et al. (1967), Abramson (1969), T Palva et al. (1970 b), Paparella et al. (1970) Abramson & Gross (1971) and T Palva et al. (in press) So far however no enzymological explanation has been found for the epithelial changes in connection with middle ear inflammation. The most remarkable enzymologic finding to date is perhaps that by Abramson (1969) and Abramson & Gross (1971) viz. the pronounced collagenase activity of the cholesteatoma membrane (epithelium plus mesenchyma), which confirms the opinion (Lautenschläger 1927; McKenzie, 1931 Walsh, 1951 1953 Harris, 1962) that the cholesteatoma has a capacity for lytic expansion.

3 CHOLESTEATOMA (EPIDERMOSIS) AND ITS ETIOLOGY

Cholesteatoma, or epidermosis (Tumarkin, 1958 1961), refers to the expansive process formed by the hyperkeratotic squamous epithelium and the underlying connective tissue. Despite assiduous research and numerous theories, the etiology of cholesteatoma is still an unresolved question. Full unanimity has not even been reached as to whether cholesteatoma is the cause or result of an inflammation (see McGuckin, 1962)

2.3.1 *The epidermoid theory (congenital cell inclusions)*

Cholesteatoma has been ascribed by many to congenital epithelial cell inclusions in the areas concerned (e.g. Körner 1899 McKenzie, 1931 Teed, 1936 Diamant, 1937 1948 1952, 1953) This theory has today been practically replaced by the assumption of an acquired etiology Primary congenital cholesteatoma does occur but only rarely in the middle ear spaces (Eggston & Wolff 1947) Case reports have been published e.g. by Lucae (1873), Kuhn (1891), Schwartze (1896) Erdheim (1905), Grove (1929) Lindsay (1934), M. D Friedman & Quittner (1938) Holmes (1938) Cawthorne & Griffith (1961), Cawthorne (1963) Derlacki & Clemis (1965), Derlacki, Harrison & Clemis (1968) and Kärja & Laine (1970)

2.3.2. *The traumatic theory*

Through surgical or other trauma, epidermal material may be immigrated or implanted into middle ear spaces (e.g. Thulin, 1947 Nilsson, 1948 Kelemen, 1950 Escher 1954 Schroer 1958 Beichert, 1958 Seiferth, 1961) Traumatic etiology is generally accepted, although it explains only a fraction of the cases of cholesteatoma.

2.3.3 *The metaplastic theory*

2.3.3.1 Suppuration

According to Wendt (1873) chronic inflammation could cause squamous metaplasia of the middle ear epithelium, leading even

to keratinization and cholesteatoma. Although squamous epithelial metaplasia is a generally accepted and verified phenomenon histologically this kind of cholesteatoma genesis has not been possible to verify as yet. However several reports have been published even recently on metaplastic squamous epithelium found in a chronically infected middle ear (Bendek, 1963 Zechner 1965 1966 Sadé & Weinberg 1969 Sadé 1971) and some has been found to be of a keratinizing type (Bendek 1963 Sadé & Weinberg 1969 Sadé, 1971) Sadé (1971) advocates the metaplastic etiological mechanism of cholesteatoma but admits that more than one etiology is possible.

2.3.3.2 Desiccation

Wingrave (1910) found that air entering the antro-tympanum through tympanic membrane perforation reduces the temperature and humidity of the middle ear space with the result that *the mucous membranes are* desiccated If the desiccation continues long enough it stimulates the epithelium towards transformation into squamous epithelium and the final result of the process is cholesteatoma. This theory has not found supporters as it presupposes that the cholesteatoma does not develop until inflammation has ceased and the ear with a large permanent perforation of the drum membrane has become dry

2 3 4 *The immigration theories*

A common feature in the supposition that cholesteatoma will not develop unless the stratified squamous epithelium of the drum membrane or of the adjacent ear canal immigrates into the middle ear space. The immigration theory with its modifications, is the most widespread and accepted theory of the genesis of cholesteatoma.

Habermann and Bezold in 1888 (cited by Portman, 1963) said that acute necrotizing otitis provoked immigration of the ear canal epithelium through epitympanic perforation. Bezold (1890) considered that the basic cause was the occlusion of the Eustachian tube which produced an invagination and rupture of Shrapnell s membrane and an immigration of epidermis into the epitympanum followed by the formation of cholesteatoma According to Wittmaack (1926) this cholesteatoma presupposed hyperplasia of the middle ear mucosa due to asymptomatic neonatal otitis and invagination and the possible rupture of the ear drum caused by the resulting low pressure Consequently cholesteatoma could expand without perforation, merely by means of a 'biological factor stimulating epidermal growth Furthermore a number of the cholesteatomata developed secondarily after necrotizing otitis (and the resulting total defect of the drum) Views in agreement with those of Wittmaack have later been advanced e g by Almour (1930) Day (1941) Jordan (1963) and Juers (1965) According *to them however the invagination* had to cause a rupture if a (primary acquired) cholesteatoma were to be formed Also Day *(1934 1941) Jordan (1963) and Juers (1965)* emphasized the role of humidity in stimulating desquamation and in causing and accelerating the growth of cholesteatoma.

Politzer (1901) already pointed out the considerable growth tendency of the epidermis of Shrapnell s membrane and the epidermis of the nearby ear canal (also Manasse, 1917) as a condition for the genesis of acquired cholesteatoma Nager (1925) Hellman (1925) and Lange (1925 1932) claimed that the basal cell layers of the epidermis of Shrapnell s membrane proliferated owing to chronic irritation The developing epidermal projections invaded the submucosa of Prussak s space (Lange) in the middle ear thus forming a "basis of cholesteatoma Similar changes were described by Steurer (1929 1950) Albrecht (1931 1950) and Schwarz (1932) Albrecht & Schwarz (1933) emphasized the role of the epitympanic connective tissue rests in the *formation of*

Shrapnell's cholesteatoma the process could be triggered off e.g. by a simple eczema of the ear canal (Steurer 1929 Albrecht, 1950), or a tubal catarrh (Steurer 1929 Schwarz, 1962).

When the ear canal or middle ear was experimentally irritated by various chemical agents (Berberich, 1927 Hoshiya, 1935 Schröer 1957) it was found that the epidermis of the ear canal proliferated and grew through a paracentetic hole or spontaneous perforation, into the middle ear forming cholesteatoma. Friedmann (1955 a, b) infected the tympanic bulla of guinea pigs and found that keratinizing squamous epithelium migrated through the perforated tympanic membrane and formed a cholesteatoma. Rüedi (1959), with a mixture of talc and fibrin, provoked an experimental foreign body reaction in the middle ear of guinea pigs with intact ear drums. He saw acanthosis and hyperkeratosis in ear drum epidermis which immigrated to form a cholesteatoma behind the intact tympanic membrane.

Rüedi (1957 1958 1959 1963 1965) stated that all acquired middle ear cholesteatomata developed as a result of an immigration of the epidermis of the ear canal or the drum, regardless of whether the tympanic membrane was intact or not. Predisposing factors were the elevated growth potential (in early childhood) of the skin of the superior ear canal close to the tympanum, and the submucosal connective tissue in the middle ear spaces resulting from incomplete pneumatization. Neither Friedman (1955 b) nor Rüedi (1958) observed in their experimental studies any sign of squamous epithelial metaplasia or cholesterol granuloma in the guinea pig bulla. According to Ojala & Saxén (1952) the connective tissue layer of the normal Shrapnell's membrane inhibits immigration. For a cholesteatoma to develop it is therefore necessary that the normal correlation between epidermis and corium should have been destroyed by an inflammatory process. Immigration and genesis of cholesteatoma could then take place through openings in the corium of imperforated pars flaccida or one perforated during inflammation. The prerequisite of cholesteatoma in both cases is the type of the mucosa it must be hyperplastic. If the mucosa is too fibrous (cicatricial), the epidermis cannot grow into it. Thus the cases with "*inferior*" mucosal constitution and recurrent otitic processes in childhood are particularly prone to cholesteatoma formation.

to keratinization and cholesteatoma. Although squamous epithelial metaplasia is a generally accepted and verified phenomenon histologically this kind of cholesteatoma genesis has not been possible to verify as yet. However several reports have been published even recently on metaplastic squamous epithelium found in a chronically infected middle ear (Bendek 1963 Zechner 1965 1966 Sadé & Weinberg 1969 Sadé, 1971) and some has been found to be of a keratinizing type (Bendek 1963 Sadé & Weinberg 1969 Sadé 1971) Sadé (1971) advocates the metaplastic etiological mechanism of cholesteatoma but admits that more than one etiology is possible.

2.3 3.2 Desiccation

Wingrave (1910) found that air entering the antro-tympanum through tympanic membrane perforation reduces the temperature and humidity of the middle ear space, with the result that the mucous membranes are desiccated. If the desiccation continues long *enough it stimulates the epithelium towards* transformation into squamous epithelium and the final result of the process is cholesteatoma. This theory has not found supporters as it presupposes that the cholesteatoma does not develop until inflammation has ceased and the ear with a large permanent perforation of the drum membrane has become dry

2.3 4 *The immigration theories*

A common feature is the supposition that cholesteatoma will not develop unless the stratified squamous epithelium of the drum membrane or of the adjacent ear canal immigrates into the middle ear space The immigration theory with its modifications, is the most widespread and accepted theory of the genesis of cholesteatoma

Habermann and Bezold in 1888 (cited by Portman 1963) said that acute necrotizing otitis provoked immigration of the ear canal epithelium through epitympanic perforation Bezold (1890) considered that the basic cause was the occlusion of the Eustachian tube which produced an invagination and rupture of Shrapnell s membrane and an immigration of epidermis *into the epitympanum followed* by the formation of cholesteatoma. According to Wittmaack (1926) this cholesteatoma presupposed hyperplasia of the middle ear mucosa due to asymptomatic neonatal otitis and invagination and the possible rupture, of the ear drum caused by the resulting low pressure Consequently cholesteatoma could expand without perforation merely by means of a 'biological factor stimulating epidermal growth Furthermore, a number of the cholesteatomata developed secondarily after necrotizing otitis (and the resulting total defect of the drum) Views in agreement with those of Wittmaack have later been advanced e g by Almour (1930) Day (1941), Jordan (1963) and Juers (1965). According to them however the invagination had to cause a rupture if a (primary acquired) cholesteatoma were to be formed Also, Day (1934 1941) Jordan (1963) and Juers (1965) emphasized the role of humidity in stimulating desquamation and in causing and accelerating the growth of cholesteatoma.

Politzer (1901) already pointed out the considerable growth tendency of the epidermis of Shrapnell s membrane and the epidermis of the nearby ear canal (also Manasse, 1917) as a condition for the genesis of acquired cholesteatoma Nager (1925) Hellman (1925) and Lange (1925 1932) claimed that the basal cell layers of the epidermis of Shrapnell s membrane proliferated owing to chronic irritation The developing epidermal projections invaded the submucosa of Prussak s space (Lange) in the middle ear thus forming a "basis of cholesteatoma Similar changes were described by Steurer (1929 1950) Albrecht (1931 1950) and Schwarz (1932) Albrecht & Schwarz (1933) emphasized the role of the epitympanic connective tissue rests in the formation of

of myelin sheaths, was used. According to the method developed by Pearse (1956), the staining was effected with the Luxol Fast Blue solution, using lithium carbonate for differentiation and warm cresyl echt violet solution for counterstaining.

This method gave the phospholipids a turquoise colour.

Baker's acid hematein staining

Baker (1946) modified the Smith-Dietrich method (Dietrich 1910) to increase its specificity to phospholipids. Under this method, after potassium bichromate-calcium chloride treatment, the sections were stained with Baker's acid hematein solution. The sections were then washed, and differentiation took place in borax potassium ferricyanide solution. No prefixative phospholipid extraction was carried out.

The underlying principle of this method is that phospholipids are easily bound with chromium salts into insoluble compounds which, with acid hematein, stain blue black to black.

Ladewig's modification of Mallory's staining

The sections were first stained with Weigert's haematoxylin solution, washed with water and placed in 5 per cent phosphotungstic acid solution for 1—3 minutes (until the connective tissue showed pink rose colour). They were then re-washed with water and placed for 2 minutes into Ladewig's staining solution [Composition: ½ g water-soluble aniline blue + 2 g Orange G + 8 cc glacial acetic acid + 100 cc distilled water. The mixture is boiled, filtered and cooled, 1 g acid fuchsin (Rubin S) is added, and filtered]. After this the sections were quickly rinsed in water and placed directly into 95 per cent alcohol, where they were differentiated until all excessive aniline blue came off.

In addition to the characteristics typical of the normal Mallory's staining, this modification gives a reddish-violet colour to keratin and keratohyalin granules in the squamous epithelium. This is apparently because the keratin disulphide groups and the sulphhydryl groups of the immature keratin have better affinity to Ladewig's modification.

Ayoub-Shklar's modification of Mallory's staining

Ayoub & Shklar (1963) developed a method based on Mallory's connective tissue staining, to stain keratin and pre-keratin. This method for formalin-fixed specimens omits the Mallory stages with the alcoholic iodine solution and the sodium thiosulphate solution necessary for Zenker-fixed specimens. The acid fuchsin solution used had ten times higher concentration than in Mallory's method. According to Ayoub & Shklar, this method stains keratin brilliant red and the epithelium purple gray. Stratum spinosum also sometimes shows areas of orange staining suggesting pre-keratin.

These keratin stainings were used in order to stain specifically epithelial phospholipids, keratin (and pre-keratin), and in this way to obtain information on the type and degree of keratinization of tympanic squamous epithelium.

3 MATERIAL AND TECHNIQUES

3.1 MATERIAL

The material comprised 13 chronically in flamed middle ears. It was collected from September 1967 to March 1969 by daily examination of the ears of the deceased un dergoing autopsy at the Department of Pathology University of Oulu. All temporal bones with signs of chronic middle ear processes were removed The cadavers had been in cold storage for 13—91 (mean 58) hours before the autopsy

3.2 TECHNIQUES

3.2.1 *Preparation of sections*

The removed temporal bones were fixed in phosphate-buffered 10 % formalin solution where they remained for 1—9 months. The fixation fluid was changed at 2—3 month intervals.

Before decalcification the removed temporal bones were trimmed with a saw so that the first sawing line passed to the side of the ear drum cutting the ear canal close to the tympanum, and the second sawing line medially of the pars petrosa of the temporal bone leaving the whole middle ear in the block. The other sawing directions intersected the former transversely so that the tympanic half of the Eustachian tube was included, and on the mastoid side the preparation was cut at the level of the vertical part of the facial canal.

The decalcification took place in 22.5 % formic acid sodium citrate solution which was changed twice weekly The period of decalcification, depending on the hardness of the block, ranged from 6 to 8 weeks.

The celloidin-paraffin double embedding method was used. The middle ear blocks were sectioned with rotary microtome (Leitz Wetzlar) vertically so that the cutting line ran frontally corresponding to a line from the ear drum towards the promontory The section always started at the orifice of the Eustachian tube and continued posteriorly to the vertical part of the facial canal. The order of sectioning and staining was the following

1 3 sections, 10 μ thick, were stained with Haematoxylin-Eosin (H E)
2. 2 sections, 25 μ thick, were discarded
3 3 sections, 10 μ thick, were used for mucus and keratin stainings
4 3 sections, 10 μ thick, were stored for later staining
5 2 sections, 25 μ thick, were discarded
1 3 sections, 10 μ thick, were stained with H E, and so on, in the same order as above

3.2.2 *Staining methods*

3.2.2.1 Routine staining

Haematoxylin-Eosin (H E) staining (Harris)
The systematic study and analysis of the middle ear mucosa was made from sections stained with haematoxylin-eosin. In this way the structure of the middle ear at 160 μ intervals, was investigated.

3.2.2.2 Mucus stainings

Periodic Acid Schiff (PAS) staining according to the MacManus method
According to Leblond et al. (1957) PAS-positive reaction in paraffin sections after the removal of glycogen is obtained only from the carbohydrate-protein complexes. However the method of staining used did not include a diastase digestion, and therefore the polysaccharides also gave a PAS-positive reaction (Magenta).
Alcian Blue (AB) staining
The sections were stained in Alcian Blue 7 G solution (30 minutes) and counterstained with Kernechtrot solution (5 minutes). The method used did not include a hyaluronidase phase This method, together with the PAS staining was used mainly to study the epithelial secretory function.

3.2.2.3 Keratin stainings

Alcian Copper Phthalocyanine staining
A copper phthalocyanine compound developed by Fisher & Barrera (1953 1954) called Luxol Fast Blue (Dupont) originally intended for the staining

4 CASE REPORTS AND HISTOLOGICAL FINDINGS

This chapter gives a detailed description of all the 13 middle ears examined by serial sections and various staining methods. Altogether about 8000 sections were examined and special attention was paid to the characteristics of the middle ear epithelium.

The squamous epithelium seen in the tympanum is classified as immigrating or metaplastic (see Discussion) The immigrating type refers to squamous epithelium which is in continuity with the ear canal epidermis. The metaplastic type refers to squamous epithelium that is independent, without connection or junctional with connection to the immigrating squamous epithelium The change of normal epithelial type seen in a certain place in the middle ear is called metaplasia even if the change is too slight to permit the determination of this final type.

4 1 TEMPORAL BONE 1

The patient had died of coronary thrombosis at the age of 85 years He had been deaf for many years, but no other otologic history was available. Otoscopy revealed profuse discharge and an extensive central perforation of the pars tensa in the left ear

4 1 1 *Histology*

The central perforation of the pars tensa had a diameter of about 5 mm (Fig 1) The remaining parts of the drum membrane were 0.2—0.3 mm thick. The squamous epithelium of the ear canal grew over the lower edge of the perforation and after an abrupt junction at the edge continued onto the tympanic side of the drum for 0.3—0 4 mm as thin metaplastic squamous epithelium (Figs 4 5) Metaplasia then became weaker and the epithelium continued resembling a 2—3 layered cuboidal epithelium to the lower posterior part of the tympanum where it gradually changed into typical cuboidal epithelium In the anterior lower parts of the tympanum, the squamous epithelium underwent an abrupt change into slightly metaplastic cuboidal and at a distance of 0.5 mm, ciliated columnar epithelium (Fig 6) In the upper margin of the perforation the squamous epithelium of the ear canal crossed over into the tympanic side for 0 1—0 [illegible] mm (Figs 2 3) Immediately before the perforation edge the squamous epithelium lost its stratum granulosum, and after a short intermediate phase as squamous epithelium on the tympanic side of the drum, it continued as metaplastic cuboidal and low columnar epithelium

The incus was absent and all that remained of the malleus was its head with a bony

4 CASE REPORTS AND HISTOLOGICAL FINDINGS

This chapter gives a detailed description of all the 13 middle ears examined by serial sections and various staining methods. Altogether about 8000 sections were examined and special attention was paid to the characteristics of the middle ear epithelium.

The squamous epithelium seen in the tympanum is classified as immigrating or metaplastic (see Discussion). The immigrating type refers to squamous epithelium which is in continuity with the ear canal epidermis. The metaplastic type refers to squamous epithelium that is independent, without connection or junctional with connection to the immigrating squamous epithelium. The change of normal epithelial type seen in a certain place in the middle ear is called metaplasia even if the change is too slight to permit the determination of this final type.

4.1 TEMPORAL BONE 1

The patient had died of coronary thrombosis at the age of 85 years. He had been deaf for many years, but no other otologic history was available. Otoscopy revealed profuse discharge and an extensive central perforation of the pars tensa in the left ear.

4.1.1 *Histology*

The central perforation of the pars tensa had a diameter of about 5 mm (Fig. 1). The remaining parts of the drum membrane were 0.2—0.3 mm thick. The squamous epithelium of the ear canal grew over the lower edge of the perforation and after an abrupt junction at the edge continued onto the tympanic side of the drum for 0.3—0.4 mm as thin metaplastic squamous epithelium (Figs. 4, 5). Metaplasia then became weaker and the epithelium continued resembling a 2—3 layered cuboidal epithelium to the lower posterior part of the tympanum where it gradually changed into typical cuboidal epithelium. In the anterior lower parts of the tympanum, the squamous epithelium underwent an abrupt change into slightly metaplastic cuboidal and at a distance of 0.5 mm, ciliated columnar epithelium (Fig. 6). In the upper margin of the perforation the squamous epithelium of the ear canal crossed over into the tympanic side for 0.1—0.2 mm (Figs. 2, 3). Immediately before the perforation edge the squamous epithelium lost its stratum granulosum, and after a short intermediate phase as squamous epithelium on the tympanic side of the drum it continued as metaplastic, cuboidal and low columnar epithelium.

The incus was absent, and all that remained of the malleus was its head with a bony

Fig. 6. 0.6 mm anteriorly to the Fig. 1 level. The squamous epithelium (SQ) immigrates at the lower perforation margin onto the tympanic side and is changed, in the lower lateral area of the tympanum, over a short (0.3 mm) metaplastic zone (M) into ciliated columnar epithelium (R). H—E 160 x.

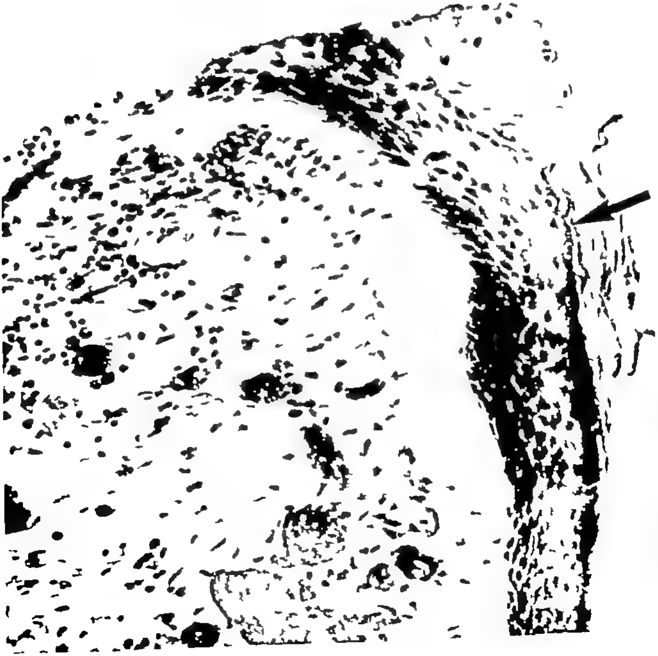

Fig. 6. 0.6 mm anteriorly to the Fig. 1 level. The squamous epithelium (SQ) immigrates at the lower perforation margin onto the tympanic side and is changed, in the lower lateral area of the tympanum, over a short (0.3 mm) metaplastic zone (M) into ciliated columnar epithelium (R). H—E 160 x.

Fig. 7. Low columnar epithelium, with verifiable cilia, from the upper lateral part of the posterior tympanum. A secretory film is seen on top of the ciliary layer. H—E 400 x.

union to the roof of the epitympanum. The cariotic stapes was surrounded by fibrous tissue.

The promontorial epithelium was cuboidal with 1—3 layers, and in some areas it even changed into flat endothelium like lining. In the posterior part of the middle ear the epithelium was highest at the floor where some of the epithelium had undergone a mucous change. Hardly any secretory cells were seen in the tympanum. The tympanic mucosa was thick and oedematous. Only in the medial wall was it somewhat fibrotic.

The anterior tympanum showed not only cuboidal and low columnar epithelium but also especially in the roof and in the lower parts, metaplastic type epithelium (the epithelium was multilayered, the epithelial cells and nuclei were disorganized, cytoplasm had shrunk, and cellular eosinophilia had increased in H E staining). Backwards the metaplasia disappeared, and was only seen in the neighbourhood of the perforation edges and over a small area in the upper medial wall of the posterior tympanum. At the orifice of the Eustachian tube, the epithelium was largely of the respiratory type. A strip of ciliated cells continued from the tube posteriorly in the lower and upper lateral parts of the middle ear to the posterior tympanum (Fig. 7). Also, a small strip of ciliated cells was seen on the luminal roof to the level of the posterior part of the promontory.

Keratin stainings of the tympanic epithelium were negative. The minute keratin debris seen on the tympanal side of the perforation edges had obviously entered the tympanum from the ear canal side during processing.

The weak positivity of the mucus stains was localized mainly in the area of the higher epithelium of the hypotympanum. AB positivity was clearly weaker than PAS-positivity. The squamous epithelium was AB- and PAS-negative.

4.2 TEMPORAL BONE 2

The patient had died at 56 of cerebral haemorrhage complicating acute myeloblastic leucaemia. He had had discharge from his left ear periodically for 40 years. Otoscopy disclosed slight discharge and an extensive perforation of the pars tensa in the left ear.

4.2.1 *Histology*

The central perforation comprised practically the whole pars tensa, a good millimetre wide remnant (Fig. 8) of the thickened (0.2—0.5 mm) drum membrane remaining throughout. Its posterior part adhered to the medial wall of the tympanum (Fig. 10). The squamous epithelium of the ear canal grew over the perforation edges for a short distance onto the tympanic side of the drum membrane (Fig. 9). This ingrowth was most pronounced at the lower edge where the squamous epithelium extended up to 0.5 mm onto the tympanic side. However, it lost the surface keratin and stratum granulosum on the ear canal side just before the annular edge, cuboidal columnar epithelium lining the abundant granulations of this area. The Tympanic epithelial changes were difficult to evaluate since the *oedematous middle ear*

mucosa showed granulation tissue and areas of epithelial defects. It seemed, however that the squamous epithelium changed through a short (up to 0.5 mm) low metaplastic phase into cuboidal and columnar epithelium of the middle ear (Figs. 16—18).

In the anterior and superior margin of the perforation, the squamous immigration was almost absent. In the posterior margin, the squamous epithelium, having lost its granular and keratin layer immigrated along the adhesions into the medial wall of the posterior tympanum (Figs. 10—13). There this squamous epithelium was widely stratified and contained even prickle cells. In some places, it showed pseudoparakeratosis, i.e. parakeratotic scaling of superficial cells with their nuclei but without any sign of keratin in the squamous epithelium (Figs. 14 15). At a distance of about 2 mm from the drum edge the squamous epithelium changed into slightly metaplastic and, further on, into promontory was lined throughout with 1—3 layered cuboidal and in places columnar epithelium.

The middle ear epithelium was generally low cuboidal with 1—3 layers, and in some places even endothelium-like. The higher columnar epithelium, also seen in the tympanum was irregular throughout, and numerous detached columnar cells were seen. The columnar epithelium was localized particularly in pouches and in hypotympanic air cells opening into the middle ear and in the anterior tympanum. Also, early stages of metaplastic epithelium were varyingly seen throughout the tympanum in the form of hyperplasia, increased disorganization, deformity and increased eosinophilia of the cells.

No true glands or secreting cells were seen in the tympanum. There were a few cysts and pseudocysts mainly in the posterior parts. The auditory ossicles were carious. The thickened, remarkably oedematous mucosa of the middle ear was infiltrated by inflammatory cells.

The discontinuous epithelium of the anterior tympanum was largely columnar and, mainly in its roof and floor covered by cilia. No distinct strips of ciliated cells were visible. The cilia were most numerous in the lower parts of the tympanum and even there they ended posteriorly at the level of the anterior margin of the drum membrane. The Eustachian tube was covered by respiratory ciliated epithelium.

The areas of squamous and metaplastic epithelium in the middle ear failed to stain positively for keratin. The tympanic epithelium stained weakly with PAS, and hardly at all with AB. The cystic cavities were AB- and PAS-positive.

4.3 TEMPORAL BONE 3

This patient of 70 had died of carcinoma of the liver. He had had chronic otitis media on the right for years. Otoscopy revealed a profusely draining central perforation of the pars tensa.

4.3.1 *Histology*

A central perforation, 3.5 mm wide and c. 3 mm high, downward from the umbo level was seen in the pars tensa (Fig. 19). The

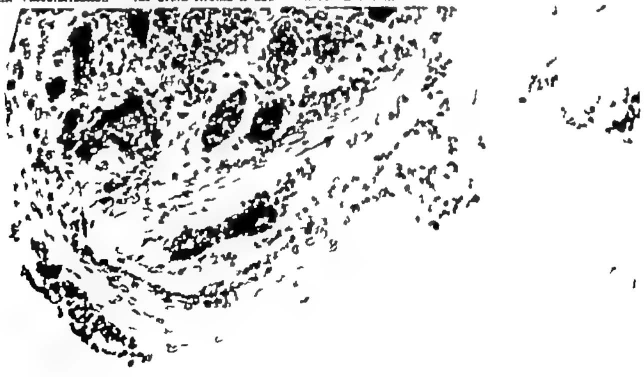
Fig. 20 The upper margin of perforation and handle of the malleus, also seen Fig 19 The squamous epitheli m continues for a short distance onto the tympanic side (arrow) H—E 40 x.

Fig. 21 A closer view of the perforation edge seen in Fig. 20. Stratum gra losum and keratin cover are absent from the immigrating squamous epithelium, a d atypia caused by nflammation is seen the epithelial cells. Vascularization the drum stroma is abu da t. H—E 160 x.



remaining drum was 0.2—0.3 mm thick. In the inferior margin of the perforation, the ear canal epidermis continued as squamous epithelium —3 layers thick (Fig. 22) onto the tympanic side of the drum for up to 1.0 mm, at its furthest extent reaching the lateral side of the inferior tympanum. All along the perforation edges, the epidermis lost its stratum granulosum on the ear canal side of th drum surface. No strata or keratini zation typical of epidermis, was seen on the surface of the squamous epithelium that had immigrated onto the tympanic side. In the upper edge of the perforation (Figs. 20, 21), the squamous epithelial immigration was similar in type and extent to that in the lower edge, while in the anterior and posterior edges it was of shorter extent. On the middle ear side after a short meta plastic phase, the squamous epithelium continued as cuboidal and respiratory epithelium, showing atypia due to active in flammation. On the ear canal side, perinuclear vacuolization was seen in the epidermis and inflammatory changes were also visible subepidermally

Pronounced inflammatory atypia was seen in the epithelium of the promontory and the whole middle ear cleft. In the area of the fossa ovalis, the epithelium had under gone a metaplastic change (independent metaplasia) into squamous epithel um a few (1—3) cell layers thick (Fig. 23). Similar epithelium was also seen on the mucosa of the roof of the middle ear space. However this could ha e been flat epithelium transformed by nflammatory atypia. Further more d stinct metaplastic areas without squamous arrangement were seen on the promontory surface (Fig. 24) and a small area on the floor of the anterior tympanum. There were extensive granulating surfaces (Fig. 25) and intensive organization processes which caused some difficulty in the determination of detailed localization and extent of the different forms of epithelium. However the respiratory type of epithelium seemed to be localized, in particular hypotympanally

In the anterior tympanum the respiratory epithelium had also retained its morphology more so in the lower parts. In the upper half of the anterior tympanum the epithelium showed prominent inflammatory atypia. In the upper lateral part flat epithelium of 1—2 layers was seen. In the roof the ciliated cells continued as two narrow strips which proceeded posteriorly to the umbo level. In feriorly the ciliary lining was more extensive and reached the level of the posterior part of the drum membrane. At the orifice of the Eustachian tube the epithelium was respira tory the cilia still being partly absent superiorly

The mucosa of the middle ear was consi derably thickened and, especially in the pouches, oedematous. Numerous organization processes of varying degree were seen. The subepithelium was infiltrated by inflamma tory cells. There were many pseudocysts. The auditory ossicles were cariotic and covered by thick mucosa.

Keratin stainings gave positive results neither for the tympanic metaplastic squa mous epithelium nor for the immigrating squamous epithelium from the drum membrane.

The tympanic epithelium stained weakly with PAS (the apical parts of some higher cells) and scarcely at all with AB Some PAS-positive granules were noted in the upper parts of the immigrating epidermis.

4 4 TEMPORAL BONE 4

This patient had a history of pulmonary tuberculosis and had died at 59 in a chest hospital of a severe respiratory infection He had had impaired hearing in both ears. Otoscopy revealed an extensive central perforation of the pars tensa in the left ear drum Foul smelling discharge was found in the ear

4 4 1 *Histology*

Anteriorly and inferiorly the remnants of the drum membrane were less than 1 mm and posteriorly 2 mm wide. Vertically the perforation measured about 5 mm (Fig 26) The drum remnants, 0.5—1 0 mm thick were increasingly fibrotic posteriorly and ultimately slightly tympanosclerotic Granulation tissue was seen at the lower edge of the perforation (Fig 27)

The squamous epithelium of the ear canal immigrated around the lower part of the perforation edge losing the stratum granulosum and its other epidermal characteristics just at the perforation edge It continued on the tympanic side of the remaining drum for some tenths of millimetres as squamous epithelium of 2—5 layers, and then changed into metaplastic (Fig 28) and in the lower medial angle of the drum into columnar partly ciliated epithelium (Fig 29) In the superior and posterior margin of the perforation the squamous epithelial immigration was very slight, and the squamous epithelium ended at the perforation edge (Fig 30) In the upper margin the squamous epithelium showed some tendency to growth in depth and sent projections of some 0.2 mm in length into the subepithelial connective tissue (Figs 31 32) In the junctional area the change was abrupt the epidermis changing into metaplastic and/or cuboidal epithelium losing its granular and keratin layer 0 1—0 2 mm before the junction (Figs. 31 32)

Squamous epithelial immigration was most pronounced in the anterior margin of the perforation where the epidermis grew up to 0 7—0 8 mm onto the tympanic side there losing its keratinizing epidermal character and was then transformed into metaplastic epithelium

The epithelium of the promontory was metaplastic (independent metaplasia) with eosinophilia in H E staining with disorganization (Fig 35) and stratification (Fig 36) of the epithelial cells. The cells showed a squamous structure in places, although the epithelium had nowhere undergone the metaplastic change into true squamous epithelium In the upper parts of the promontory this epithelium was relatively thin 2—3 cell layers, changing in the lower parts into considerably thicker epithelium In the hypotympanum its morphology began to suggest a respiratory origin being partly lined by cilia

Slightly metaplastic epithelial lining was also widely seen elsewhere in the tympanal area Besides the promontory the tympanic floor and the medial surface of the perforation edges showed the most pronounced metaplastic changes The mucosa of the upper posterior part of the middle ear was lined by a low cuboidal epithelium of 1—2 layers (Fig 33)

The whole tympanal mucosa was thickened hyperplastic and especially meso- and hypotympanally hyperaemic The auditory ossicles were cariotic The lenticular process and a part of the long process of the incus were absent.

In the anterior tympanum the epithelium was still fairly widely metaplastic apparently respiratory in origin The change became slighter in degree towards the Eustachian tube (Fig 34) only increased eosinophilia and basal hyperplasia were seen (epithelium had 3—5 layers) From the tubal orifice onwards the epithelium assumed its

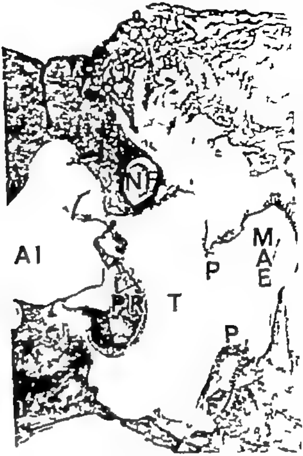

Fig. 26. General view of the tympanum. The section runs parallel to the level of the windows (MAE = meatus ac. ex., T = tympanum, AI = auris interna, NF = nervus facialis, PR = promontory, P = perforation edge.) H—E.

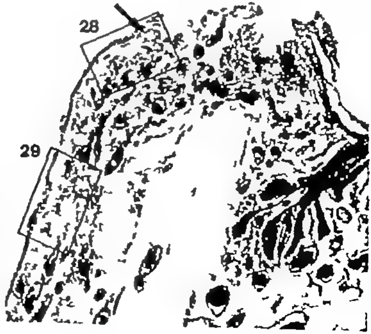

Fig. 27. A closer view of the lower margin of the perforation area in Fig. 26. The tympanal edge of the perforation shows subepithelial accumulation of squamous epithelium (arrow), from which metaplastic-type epithelium continues onto the tympanal side. The [illegible] lining perforation edge has no epithelial lining. H—E. 40.

4 4 TEMPORAL BONE 4

This patient had a history of pulmonary tuberculosis and had died at 59 in a chest hospital of a severe respiratory infection He had had impaired hearing in both ears Otoscopy revealed an extensive central perforation of the pars tensa in the left ear drum Foul-smelling discharge was found in the ear

4 4 1 *Histology*

Anteriorly and inferiorly the remnants of the drum membrane were less than 1 mm and posteriorly 2 mm wide Vertically the perforation measured about 5 mm (Fig 26) The drum remnants, 0 5—1 0 mm thick were increasingly fibrotic posteriorly and ultimately slightly tympanosclerotic. Granulation tissue was seen at the lower edge of the perforation (Fig 27)

The squamous epithelium of the ear canal immigrated around the lower part of the perforation edge losing the stratum granulosum and its other epidermal characteristics just at the perforation edge. It continued on the tympanic side of the remaining drum for some tenths of millimetres as squamous epithelium of 2—5 layers, and then changed into metaplastic (Fig 28) and in the lower medial angle of the drum into columnar partly ciliated epithelium (Fig 29) In the superior and posterior margin of the perforation the squamous epithelial immigration was very slight, and the squamous epithelium ended at the perforation edge (Fig 30) In the upper margin the squamous epithelium showed some tendency to growth in depth and sent projections of some 0 2 mm in length into the subepithelial connective tissue (Figs 31 32) In the junctional area the change was abrupt the epidermis changing into metaplastic and/or cuboidal epithelium losing its granular and keratin layer 0 1—0 2 mm before the junction (Figs. 31 32)

Squamous epithelial immigration was most pronounced in the anterior margin of the perforation where the epidermis grew up to 0 7—0 8 mm onto the tympanic side there losing its keratinizing epidermal character and was then transformed into metaplastic epithelium

The epithelium of the promontory was metaplastic (independent metaplasia) with eosinophilia in H E staining with disorganization (Fig 35) and stratification (Fig 36) of the epithelial cells The cells showed a squamous structure in places although the epithelium had nowhere undergone the metaplastic change into true squamous epithelium In the upper parts of the promontory the epithelium was relatively thin 2—3 cell layers, changing in the lower parts into considerably thicker epithelium In the hypotympanum its morphology began to suggest a respiratory origin being partly lined by cilia

Slightly metaplastic epithelial lining was also widely seen elsewhere in the tympanal area Besides the promontory the tympanic floor and the medial surface of the perforation edges showed the most pronounced metaplastic changes. The mucosa of the upper posterior part of the middle ear was lined by a low cuboidal epithelium of 1—2 layers (Fig 33)

The whole tympanal muscosa was thickened hyperplastic and especially meso- and hypotympanally hyperaemic The auditory ossicles were carious The lenticular process and a part of the long process of the incus were absent.

In the anterior tympanum the epithelium was still fairly widely metaplastic apparently respiratory in origin The change became slighter in degree towards the Eustachian tube (Fig 34) only increased eosinophilia and basal hyperplasia were seen (epithelium had 3—5 layers) From the tubal orifice onwards the epithelium assumed its

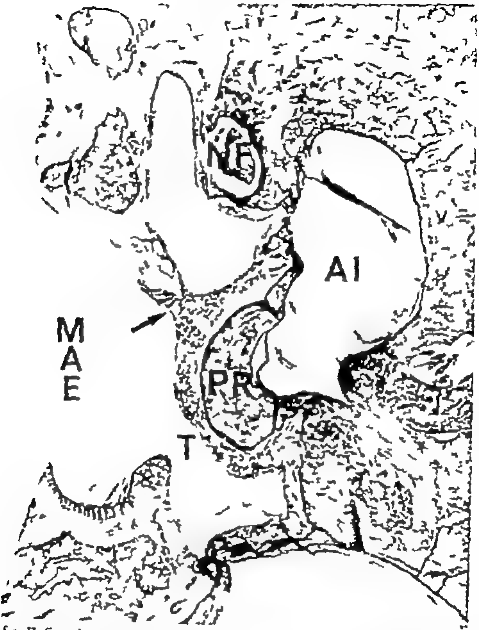

Fig. 37 General view. The whole tympanum, with thickened mucous membranes throughout, tubl. The upper edge of the ear drum perforation adheres (arrow) to the thickened, hyperaemic mucosa of the promontory (MAE = meatus ac. ext., T = tympanum, AI = aurus internus, PR = promontory, NF = nervus facialis) H—E.

normal respiratory type Tubal epithelium showed a fair amount of mucus producing cells, including goblet cells. On the middle ear side, there were mucously changed cells only hypotympanally

The almost unbroken ciliary lining of the tube continued posteriorly into the middle ear in three strips a tapering ciliary strip of some 2 mm in the roof of the lumen another in the lower medial wall extending to the middle of the promontory and a third in the lower lateral area of the tympanum to the level of the posterior part of the drum membrane.

No keratin characteristics were disclosed in the metaplastic epithelium of the tympanum With AB and PAS the metaplastic epithelium stained fairly weakly with scattered positively staining cells. The respiratory epithelium stained moderately with both stains, while the squamous epithelium was AB- and PAS-negative

4.5 TEMPORAL BONE 5

The patient's medical history is given under Temporal Bone 4 Otoscopy disclosed an extensive, central perforation of the pars tensa in the right drum membrane. The ear canal contained foul smelling discharge.

4 5 1 *Histology*

The pars tensa showed a perforation (Fig 37) 4.2 mm wide and c. 4 mm high Anteriorly and inferiorly about 1 mm of drum membrane remained and posteriorly the remnant was 2.5 mm wide. The membrane was fibrotic, 0 5—1 0 mm thick. Especially the inferior and posterior margin of the perforation was granulating infiltrated by inflammatory cells, and partly necrotic (Fig 42)

In the inferior margin the ingrowing epidermis lost its characteristics on the ear canal side of the drum and proceeded over the edge onto the tympanic side for a distance of 0 5—1 0 mm as squamous epithelium of 1—3 layers (Fig 40) Through a metaplastic zone of 0.2—0 3 mm a further change into columnar and soon into ciliated epithelium occurred (Fig 41) Although the epithelium was partly absent from the sligtly granulating surface of the lower perforation edge, the squamous epithelium could be seen to continue beyond the edge

The edge of the postero-superior quadrant of the perforation from the umbo backwards, adhered to the mucosa of the promontory (Fig 38) Along this adhesion the squamous epithelium of the ear canal immigrated to the tympanic side losing its rete pegs at the edge of the perforation It proceeded as 2—3 cell layered squamous epithelium along the partly ulcerated surface of the promontory (Fig 39) for 1.5—2 0 mm towards the anterior and inferior part of the promontory and then transformed through a metaplastic zone of 0.2—0.3 mm into columnar epithelium. Anteriorly of the adhesion in the upper free margin of the perforation the squamous epithelium changed abruptly into tympanic cuboidal epithelium

In the posterior margin of the perforation corresponding to the promontorial adhesion the squamous epithelium consisted of several layers. It had a stratum spinosum, and basally it sent projections into the underlying connective tissue e g at the oval window area, where it even formed a small subepithelial

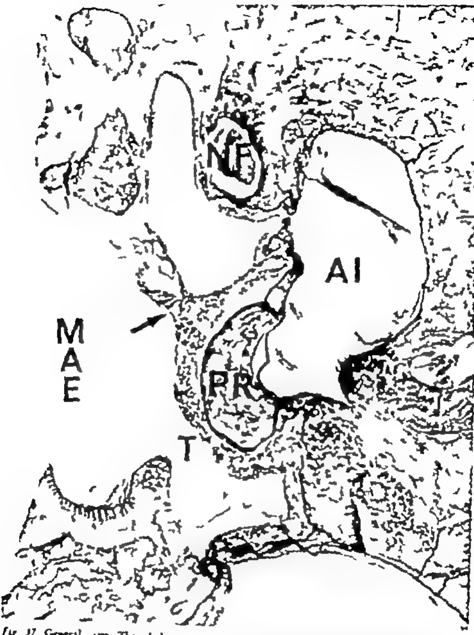

Fig 37 General view The whole tympanum, with thickened mucous membranes throughout,
visible The upper edge of the ear drum perforation adheres (arrow) to the thickened, hy
peraemic mucosa of the promontory (MAE = me tus ac ext., T = tympanum, AI = auris
interna, PR = promontory NF = nervus facialis) H—E.

normal respiratory type Tubal epithelium showed a fair amount of mucus producing cells including goblet cells. On the middle ear side, there were mucously changed cells only hypotympanally

The almost unbroken ciliary lining of the tube continued posteriorly into the middle ear in three strips a tapering ciliary strip of some 2 mm in the roof of the lumen another in the lower medial wall extending to the middle of the promontory and a third in the lower lateral area of the tympanu to the level of the posterior part of the dru membrane.

No keratin characteristics were disclose in the metaplastic epithelium of the tymp num. With AB and PAS the metaplast epithelium stained fairly weakly wi scattered positively staining cells. The resp ratory epithelium stained moderately wi both stains, while the squamous epitheliu was AB and PAS-negative

4.5 TEMPORAL BONE 5

The patient s medical history is given under Temporal Bone 4 Otoscopy disclosed an extensive central perforation of the pars tensa in the right drum membrane. The ear canal contained foul-smelling discharge

4 5 1 *Histology*

The pars tensa showed a perforation (Fig 37) 4.2 mm wide and c. 4 mm high Anteriorly and inferiorly about 1 mm of drum membrane remained, and posteriorly the remnant *was 2.5 mm wide The membrane was* fibrotic, 0.5—1 0 mm thick Especially the inferior and posterior margin of the perforation was granulating infiltrated by inflammatory cells, and partly necrotic (Fig 42)

In the inferior margin the ingrowing epidermis lost its characteristics on the ear canal side of the drum and proceeded over the edge onto the tympanic side for a distance of 0 5—1 0 mm as squamous epithelium of 1—3 layers (Fig 40) Through a metaplastic zone of 0.2—0.3 mm a further change into columnar and soon into ciliated epithelium occurred (Fig 41) Although the epithelium was partly absent from the sligtly granulating surface of the lower perforation edge the squamou epithelium could be seen to continue beyon the edge

The edge of the postero-superior quadran of the perforation from the umbo backwards adhered to the mucosa of the promontory (Fig 38) Along this adhesion the squamou epithelium of the ear canal immigrated t the tympanic side losing its rete pegs at th edge of the perforation It proceeded as 2—3 cell layered squamous epithelium along th partly ulcerated surface of the promontory *(Fig 39) for 1.5—2 0 mm towards the ante*rior and inferior part of the promontory and then transformed through a metaplastic zone of 0.2—0 3 mm, into columnar epithelium. Anteriorly of the adhesion in the upper free margin of the perforation the squamous epithelium changed abruptly into tympanic cuboidal epithelium

In the posterior margin of the perforation corresponding to the promontorial adhesion the squamous epithelium consisted of several layers. It had a stratum spinosum and basally it sent projections into the underlying connective tissue e g at the oval window area where it even formed a small subepithelial

keratin cyst (Figs. 42, 43). This squamous epithelium was not that of the promontory but that of the adhesive edge of the drum membrane. Also elsewhere along the edges of the perforation the squamous epithelium showed some tendency towards growing into depth sending projections some tenths of millimetres long into the underlying connective tissue.

In the postero-inferior margin of the perforation a squamous epithelial immigration, similar to that of the lower margin, extended about 0.5—0.6 mm onto the tympanic side of the drum membrane. In the anterior margin, the thicker squamous epithelium which had retained its stratum spinosum, grew up to 0.4—0.5 mm onto the tympanic side (Fig. 45), changing into tympanic cuboidal epithelium through a short transitional area.

The middle ear epithelium was mainly of the columnar type occasionally even 2—3 cell layers thick. In the upper part of the tympanum, there was also low cuboidal and sometimes even flat epithelium. The mucosa was thick, hyperplastic and hyperaemic. A few glands (Fig. 44) and cysts were seen and there was abundant lymphocyte infiltration of the subepithelial tissue. The auditory ossicles were cariotic. Only a remnant of the lenticular process of the incus was seen, and the connection to the head of the stapes was fibrotic.

Cilia were seen in the anterior tympanum, mainly in its lower parts, from where a hypotympanal strip of ciliated cells extended to the posterior parts of the middle ear. The medial wall showed a smaller ciliated cell track which extended to the anterior parts of the promontory.

The Eustachian tube had a complete ciliary lining with a pseudostratified columnar epithelium of the respiratory type. A few goblet cells were seen.

No keratinization, apart from the keratin cyst (see above), was detected on the tympanic immigrated squamous epithelium. Mucus stain of this epithelium did not show any positivity. The respiratory epithelium, particularly the apical parts of the cells, stained generously both with AB and PAS, however not as an unbroken carpet but interspersed with unstained cells.

4.6 TEMPORAL BONE 6

The patient had died at the age of 11 of pneumococcal meningitis which had developed as a complication to chronic otitis media on the left. Otoscopy disclosed a central perforation in the drum membrane involving approximately half the pars tensa. The tympanum was moist, no true purulent discharge was seen.

4.6.1 *Histology*

The pars tensa had a central perforation measuring 3 mm vertically and 2.5 mm horizontally. At its narrowest, the remaining drum membrane margin measured over 1.5 mm. The fibrotic remnants were thickened, up to 0.5 mm. The squamous epithelium of

Fig. 44. A gland from the inferomedial wall of the posterior tympanum. H—E 51 x

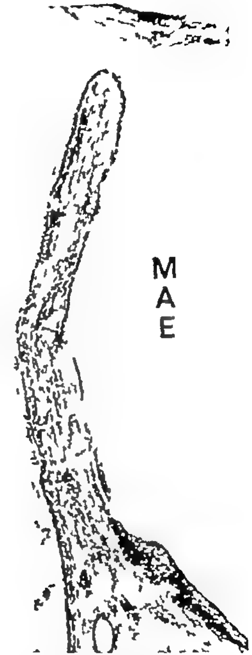

Fig. 35. The lower perforation edge some 2.1 mm posteriorly to the vertical level of the anterior perforation edge. On the ear canal side (MAE) of the drum, squamous epithelium is absent over a distance of 0.9 mm. The lining epithelium is 1—3 layered, cuboidal eversion epithelium. H—E 40 x.

F g 56 The upper perf ration edge at Fig 55 le 1 Eversion (0 1 mm) onto the ea canal side (MAE) is seen. The ear drum stroma is relatively fibrotic, yet abundantly vascularized H—E 160 x.

the ear canal did not immigrate onto the tympanal surface but transformed abruptly at the edge of the perforation into ordinary tympanic epithelium (Figs. 50—53) On the other hand, the squamous epithelium projected, just before the anterior edge of the perforation, into the ear drum stroma. It grew underneath the partly ciliated tympanic epithelium leaving a connective tissue strip 0.01—0.03 mm thick between the epithelia (Figs. 46—49) This ingrowth continued a good 1 mm forward, about 1 mm upward and about 0.2 mm downward from the anterior edge of the perforation. Elsewhere in the perforation edges no epithelial ingrowth was noted.

At the perforation edges, antero-posteriorly the cuboidal epithelium of 1—2 layers everted increasingly onto the ear canal surface of the drum remnants (Figs. 54—56). Even here, however the epidermal junction was abrupt. Posteriorly the eversion was most pronounced (up to 1.0 mm) in the inferior edge of the perforation (Fig 55) weakening upwards until, in the postero-superior edge (Fig. 56) it was 0 15 mm. In the area of the pronounced eversion, the otherwise fibrotic stroma of the drum membrane showed moderate vascularization (Fig. 56), suggesting myringitic etiology of the eversion.

The type of epithelium on the promontory and the whole tympanum, was variable. The promontorial epithelium was mainly cuboidal, metaplastic and mucously changed. The degree *of metaplasia was relatively low* its principal signs were the disorganization and hyperplasia of the epithelial cells, and the increased eosinophilia of cells in some places. Mucously changed epithelium on the promontory was confined mainly to its lower half

In addition to these epithelial types, some columnar epithelium was also seen tympanally Usually the higher (columnar mucous) epithelium was confined to the anterior and inferior parts of the middle ear and the lower cuboidal to the superior parts and antrum. The localization of the different epithelial types, however varied greatly Besides the medial wall, epithelial metaplasia was also varyingly seen at the floor of the tympanum, and also in the epitympanal space. The width of the zones of metaplasia varied from 0.1 to 1.0 mm. Nowhere in the tympanic area was there any sign of even elementary squamous epithelium.

The Eustachian tube was lined by respiratory epithelium, excepting the roof of its orifice, where the epithelium was still mucously changed. The respiratory epithelium of the tympanal tube showed extensive hyperplastic areas, up to a thickness of 5 cell layers. Posteriorly the ciliation continued infero-laterally lining also a part of the lower medial surface of the ear drum and extending as a tapering and weakening strip to the posterior part of the middle ear

The ossicular chain was intact. The tympanic connective tissue layer was slightly thickened, relatively fibrotic and showed some lymphocytic infiltration. Hardly any glands were seen. Pseudocysts were numerous, and there were adhesions indicating an organization process.

Keratin stainings showed no positive reactions on the tympanic side. The tympanic epithelium was positive to both of the two methods of mucus staining, but the response to PAS appeared slightly more pronounced.

Fig 56 The pper perforation edge t F g 55 lev l Eversion (0 1 mm) onto the ea canal side (MAE) is seen The ear drum stroma is relati ly fibrotic, yet abunda tly vascularized H—E 160

Fig 58 The lower perforation edge from he ea canal side, also seen in Fig 57 (square 58) The epidermis with all its layers extends to the abrupt junction where thickens and pushes the eversion epithelium partly off its base H—E 160

4.7 TEMPORAL BONE 7

This patient, at the age of 70 had died of hepatic coma. In the hospital it had been noticed that her left ear was draining Otoscopy disclosed a central perforation of the pars tensa. Above the perforation the ear drum adhered to the promontory and the medial wall of the tympanum Profuse purulent exudate was seen in the ear

4.7.1 *Histology*

There was a 1.5 mm high and 3 mm wide perforation of the pars tensa. The perforation edges were covered by heavily fibrotized, partly polypotic granulation tissue The tympanic epithelium containing numerous goblet and other secretory cells, but otherwise with a relatively well *retained respiratory* structure everted all over the perforation edges onto the ear canal side of the ear drum for a distance of up to 1 mm (Fig 57) At the junction the tympanic epithelium changed into epidermis either abruptly (in the lower edge, Fig 58) or through a zone of squamous *metaplasia of a maximal width of 0.5 mm* (in the upper edge, Fig 57) At many points in the junction the epidermal and the ciliated columnar cells were seen side by side All along the junction there were also places where the epidermis grew under the columnar epithelium for distances of 0 1—0 2 mm detaching the columnar epithelium from its basement membrane (Figs. 59 60) The epidermis nowhere extended to the edge of the perforation but was displaced by tympanic eversion epithelium which had developed on a *myringitic basis* (Figs 57 59)

The basal cell layer of the eversion epithelium appeared thickened throughout (Figs. 59 61) forming a stratum of cells of a squamous appearance, of 2—3 or even 5 layers This perhaps *represented* partly basal hyperplasia and partly an artifact produced by the sectioning

Above the perforation the fibrotically thickened (up to 0.5 mm) ear drum adhered to the mucosa of the upper promontorial and the oval window area, forming at the horizontal level of the *facial canal* a bridge of adhesion from the upper edge of the ear canal thus partly obliterating the epitympanum The epithelial lining of the promontory and of the tympanum on the whole, was high columnar and markedly mucous. Goblet cells were very numerous, and there were *also secretory columnar cells* and, in some places in the superficial parts of the epithelium atypical secretory cells. The tympanum showed also areas where the columnar epithelium was almost entirely replaced by the basophilic mucus epithelium. Only in the epitympanum was the epithelium *lower cuboidal and of 1—2 layers.*

In the anterior tympanum, apart from the roof the epithelium was ciliated Posteriorly with marked mucosity predominating the epithelial picture the ciliation diminished and localized itself mainly on the floor epithelium. It extended farthest as a tract *covering the medial surface* of the inferior ear drum remnants, gradually tapering into an infero-lateral strip and ending in the sinus tympani A fairly well preserved ciliary lining was also seen on the polypotic granulation tissue of the perforation edges, both on the tympanic and the ear canal side. In the Eustachian tube the epithelium was ciliated respiratory but even there the mucosity was pronounced. At the roof of the tubal orifice, the epithelium had no cilia.

Of the auditory ossicles, only a *cariotic stapes was visible* The middle ear mucosa was considerably thickened and fibrotic In the pouches the stroma was looser and oedematous. An infiltration of inflammatory cells was seen subepithelially Numerous *cysts were seen* The exudate of the middle ear lumen contained granulocytes

Keratin stainings gave no positive reactions on the tympanic side On the ear canal

side of the drum, the epidermis kept its stratum granulosum and the keratin cover up to the junction where keratin formation was partly parakeratotic in character

Mucus stainings gave a strong response in the tubal and tympanic epithelium showing AB and PAS- positivity also in the ciliated cells The metaplastic transitional areas stained considerably better with PAS The superficial parts of the epidermis close to the perforation stained faintly with PAS alone.

4 8 TEMPORAL BONE 8

This 51 year old patient had died of coronary thrombosis in a chest hospital where he had been treated for pulmonary tuberculosis He had had bilateral chronic ear disease since childhood Otoscopically the left ear showed a large nearly total defect of the pars tensa A small remnant of the fibrous annulus could be seen in all areas. There was purulent exudate in the ear canal

4 8 1 *Histology*

At the floor of the ear canal the canal epidermis grew over the fibrous annulus to the hypotympanal area retaining its epidermal characteristics for a distance of 0.3—1 0 mm (Figs 65—68) Thereafter it changed into metaplastic type epithelium of 3—5 layers which lined the main part of the hypotympanum Before reaching the promontory surface it changed into a mucous type of epithelium containing numerous goblet cells and some ciliated cells, to transform again on the promontory into metaplastic epithelium At the tympanal side of the fibrous annulus, the continuation of ear canal epidermis showed distinct subepithelial growth for a length of about 1 mm into the hypotympanal stroma (Figs 65 67 68)

In the upper edge of the perforation the remnants of the drum adhered to the malleus handle and to the long process of the incus through which a bridge of adhesions connected it to the promontory surface (Fig 62). Along this bridge the keratinizing squamous epithelium from the ear canal was seen to continue to the level of umbo and close to the long process of the partly necrotic incus. From this point it continued as a nonkeratinizing metaplastic type squamous epithelium (junction metaplasia) towards the promontory (Figs 62—64) On the promontory it proceeded as a metaplastic epithelium and changed in the posterior part of the promontory into mucus producing columnar epithelium The latter epithelium also covered the posterior hypotympanum and here the nonkeratinizing squamous epithelium (junction metaplasia) was limited to the proximity of the perforation edge (less than 1 mm distance) Taking the perforation as a whole, the keratinizing squamous epithelium immigrated for a short distance towards the tympanum then lost its granular cell layer and overlying keratin and continued as a thinner metaplastic type of non keratinizing squamous epithelium (for a distance of 0 1—1 0 mm) before changing into other epithelial types.

The tympanal mucous membrane was thick loose and oedematous Ciliated epithelium was mainly seen as two strips, one running medially on the anterior promontory

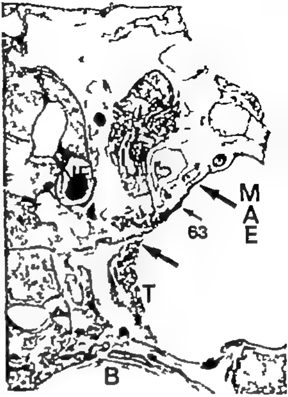

Fig 62 General view of the tympanum posteriorly to the level of the windows. Carious incus and superior adhesion (arrows) to the tympanal wall are seen. The loose stroma shows follicular lymphocyte accumulations, and the tympanic cavity contains exudate. (NF = nervus facialis, MAE = meatus ac. ext. I = incus, B = bulbus jugularis, T = tympanum.) H—E.

side of the drum the epidermis kept its stratum granulosum and the keratin cover up to the junction where keratin formation was partly parakeratotic in character

Mucus stainings gave a strong response in the tubal and tympanic epithelium showing AB and PAS- positivity also in the ciliated cells. The metaplastic transitional areas stained considerably better with PAS The superficial parts of the epidermis close to the perforation stained faintly with PAS alone.

4 8 TEMPORAL BONE 8

This 51 year old patient had died of coronary thrombosis in a chest hospital where he had been treated for pulmonary tuberculosis. He had had bilateral chronic ear disease since childhood Otoscopically the left ear showed a large, nearly total defect of the pars tensa A small remnant of the fibrous annulus could be seen in all areas. There was purulent exudate in the ear canal

4 8 1 *Histology*

At the floor of the ear canal the canal epidermis grew over the fibrous annulus to the hypotympanal area, retaining its epidermal characteristics for a distance of 0 3—1 0 mm (Figs. 65—68) Thereafter it changed into metaplastic type epithelium of 3—5 layers which lined the main part of the hypotympanum. Before reaching the promontory surface it changed into a mucous type of epithelium containing numerous goblet cells and some ciliated cells to transform again on the promontory into metaplastic epithelium At the tympanal side of the fibrous annulus the continuation of ear canal epidermis showed distinct subepithelial growth for a length of about 1 mm into the hypotympanal stroma (Figs. 65 67 68)

In the upper edge of the perforation the remnants of the drum adhered to the malleus handle and to the long process of the incus through which a bridge of adhesions connected it to the promontory surface (Fig 62). Along this bridge the keratinizing squamous epithelium from the ear canal was seen to continue to the level of umbo and close to the long process of the partly necrotic incus. From this point it continued as a nonkeratinizing metaplastic type squamous epithelium (junction metaplasia) towards the promontory (Figs. 62—64) On the promontory it proceeded as a metaplastic epithelium and changed in the posterior part of the promontory into mucus-producing columnar epithelium The latter epithelium also covered the posterior hypotympanum and here the nonkeratinizing squamous epithelium (junction metaplasia) was limited to the proximity of the perforation edge (less than 1 mm distance) Taking the perforation as a whole, the keratinizing squamous epithelium immigrated for a short distance towards the tympanum then lost its granular cell layer and overlying keratin and continued as a thinner metaplastic type of nonkeratinizing squamous epithelium (for a distance of 0 1—1 0 mm) before changing into other epithelial types.

The tympanal mucous membrane was thick loose and oedematous. Ciliated epithelium was mainly seen as two strips, one running medially on the anterior promontory

surface and the other laterally to the hypotympanum. In the anterior tympanum the medial wall was partly covered by meta plastic (independent? metaplasia) epithelium (Figs. 69—71). Antero-inferiorly it was connected to the lateral metaplastic (junction metaplasia) and squamous epithelium.

In the orifice of the Eustachian tube the mucous membrane was covered by typical ciliated columnar epithelium containing numerous basophilic secreting cells and goblet cells.

All keratin stains were consistent with the squamous epithelial immigration seen in the H E stain. Thus in the inferior margin, keratinizing squamous epithelium was seen, at a maximum, 1 0 mm on the tympanal side. In the ossicular area, the granular cell layer and overlying keratin disappeared at the umbo level The other tympanal epithelium showed no keratin-positivity

Tubal and the mucous tympanal epithelium was AB- and PAS-positive (also some ciliated cells) The columnar cells showed most intensive staining in their apical parts. Epidermis was AB- and PAS-negative strongly metaplastic epithelium was AB-negative but faintly PAS-positive. In the areas of slight metaplasia the superficial cells stained also weakly with AB.

4 9 TEMPORAL BONE 9

This patient had died at the age of 70 of bilateral bronchopneumonia. Otoscopically her right ear showed a large perforation of the pars tensa which was marginal in the infero-posterior quadrant. On macroscopic examination the tympanic mucosa was slightly thicker than normal but there was no discharge in the ear canal.

4 9 1 *Histology*

The perforation in the pars tensa measured 3 1 mm vertically and 4.8 mm horizontally The remaining pars tensa was considerably thicker than normal, measuring 0.2—0.3 mm, and showed changes typical of tympanosclerosis. Epidermis from the external side of the drum remnants grew over the perforation edges to the tympanal side (Figs. 72—77). This extension varied, so that at the superior margin the squamous epithelium extended up to 1.3 mm, at the inferior margin up to 1.7 mm and at the anterior margin up to 0 4 mm tympanally At the posterior margin, epidermis ended at the perforation edge. The change of the squamous epithelium into tympanic flat, cuboidal or even ciliated epithelium was abrupt (Figs. 73—79) At certain areas, the thick keratinizing squamous epithelium and the stratified columnar ciliated epithelium were side by side (Fig. 78) At the inferior area, the keratinizing squamous epithelium partly covered the hypotympanic stroma but, here as well, ended abruptly in a junction with the flat and thin cuboidal epithelium (Figs. 75—77). Postero-inferiorly the squamous immigration extended even to the medial wall of the tympanum. Thus the immigration seemed to take place more easily over this marginal area. When the squamous epithelium formed a junction with the tympanic epithelium on the tympanosclerotic tissue on the upper part of the drum, the tympanal epithelium resembled

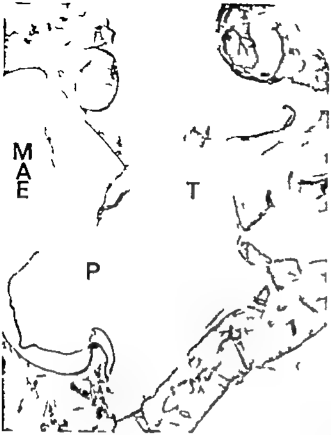

Fig. 72 General view of the tympanum. The ear canal (MAE), ear drum perforation (P) and middle ear space (T) is seen, the section level passing just posteriorly to the level of the windows. There is no active inflammatory process. Figs. 73—77 are closer views of details in the same section. H—E.

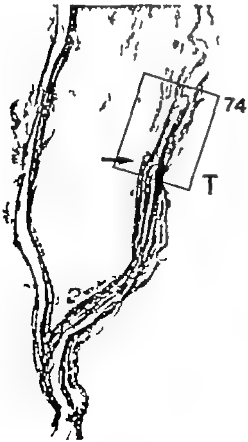
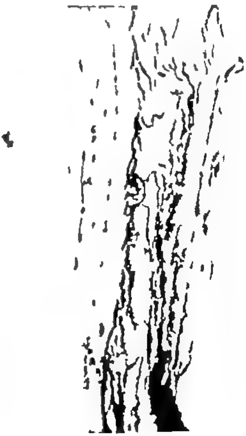
Fig 73 (bottom left) The upper margin of the perfo ration, also seen in Fig 72. The epidermis, with al its layers, immigrates onto the tympanal side (T terminat g abruptly (arrow) The ear drum remnan is tympanosclerotic. H—E 40 x

Fig 74 (bottom right) The ep dermal junction on th tympanal side of the perforation edge seen also in Fig 73 (square 74) The epidermis with its strata changes abruptly nto flat epithelium. The epiderm is slightly hyperkeratotic The underlying stroma is tympanosclerot c. H—E 160





endothelium but the junction was nevertheless sharply defined (Figs. 73 74)

Loose sheets of keratin were seen in the tympanic cavity close to the perforation. They covered the medial side of the perforation edges and partly the hypotympanic mucosa corresponding to the area of immigrating epidermis. The keratin stains demonstrated distinct phospholipid granules in the granular cell layer which ended slightly before or at the front of the advancing squamous epithelium. There was no sign of any collection of keratin debris in the middle ear and the degree of keratinization was that of the ear canal epidermis.

The promontory was covered by fibrotic 0.05—0.2 mm thick mucosa. Superiorly the promontorial epithelium was low cuboidal, or flat endothelial. Opposite to the perforation and at the inferior tympanum it changed to cuboidal epithelium with 2 or 3 cell layers. At the posterior part of the tympanum, the subepithelial tissue became thinner and was covered by a thin cuboidal or flat endothelium-like epithelium of 1—2 cell layers. In the hypotympanum, some of the epithelial cells were ciliated. Malleus, incus and stapes were intact.

In the anterior tympanum, epithelium consisted generally of 3—5 cell layers and was cuboidal without cilia. At the orifice of the Eustachian tube, and in the tube itself the epithelium had 3—10 cell layers showing in places, here as well as in the anterior tympanum, basal hyperplasia. Ciliated cells were seen particularly at the inferior areas from which ciliated narrow epithelial strips continued to the inferior tympanum and even to the posterior tympanum. In other areas ciliated cells were scarce. A few secreting cells were seen, mainly in the lateral part of the tympanal tube.

The keratin stains were consistent with the H E stain showing the immigrating squamous epithelium in the process of keratinization (and epidermal in character) up to the sharp junction with the tympanal columnar cuboidal or flat epithelium. The mucus stains were faintly positive in the Eustachian tube epithelium the tympanal area was almost devoid of positively staining epithelial cells.

4 10 TEMPORAL BONE 10

The patient's medical history is given under Temporal Bone 8. Otoscopy revealed a total perforation of the right pars tensa. The malleus handle was missing, and the ear was moist.

4 10 1 *Histology*

A fibrotic annular remnant was all that was left of the pars tensa (Fig. 80). At the postero-inferior perforation edge the epidermis extended, showing some signs of parakeratosis, over the region of the annulus, up to 0.5 mm to the tympanic side. In the hypotympanum this squamous epithelium became metaplastic (Fig. 81) and further on columnar in some places even ciliated. Elsewhere along the perforation edges the ear canal epidermis was transformed at the annular level into metaplastic epithelium, which lost its squamous character after at the most, 0.5 mm on the tympanic side of the annulus (Figs. 82—84).

The promontory was lined by metaplastic epithelium (Fig. 85), which encircled a 1.5 mm high and 2 mm wide area of squamous

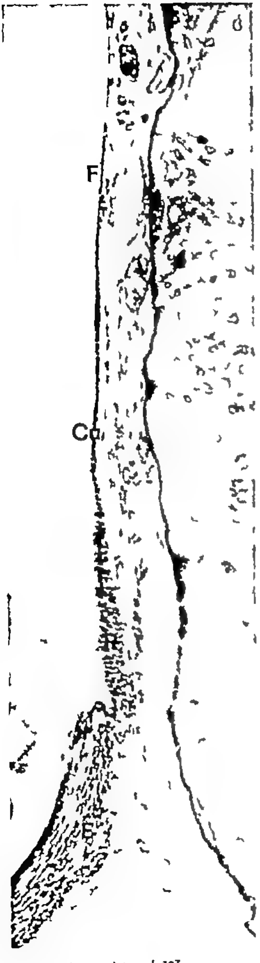


Fig 78 The squamo-columnar junction in the infero-medial p of the posterior tympanum. The epidermis (E) with its lay changes abruptly into ciliated columnar (R) and further in cuboidal (Cu) and flat, endothelial epithelium (F). At the ju tion, the epidermis seems to grow over the columnar epithelio (for up to 0.15 mm) H—E 100 x.

Fig 83 An area in Fig 80. In the upper annular region, just on the ear canal side, the squamous epithelium terminates abruptly and continues as metaplastic epithelium H—E 160

Fig 84 The upper annular region (A) in Fig 80 The epithelium has 2—3 cell layers and resembles squamous epithelium in appearance No different types of cell layers are distinguishable H—E 160

Fig 85 An area in Fig 80 The metaplastic epithelium (M) seen at the top of this figure is distinctly transformed into the squamous type (at about the middle of the promontory), with prominent basement membrane [illegible] The stroma is relatively fibrotic H—E 160

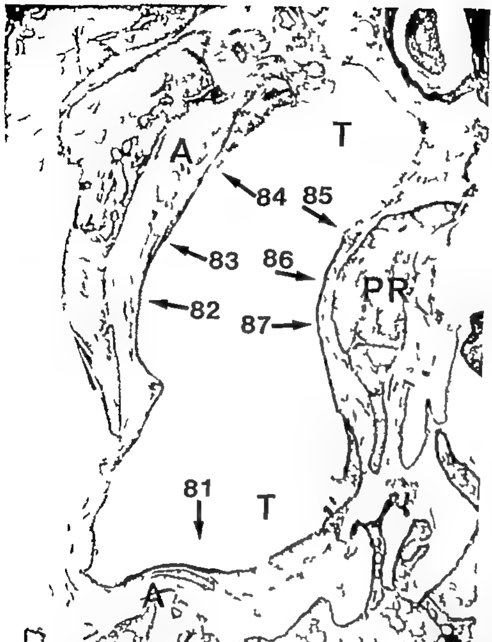

Fig 80 General view of the tympanum. The perforation is marginal, the mucous membrane of the tympanum thick, hyperaemic and oedematous. Figures 81—87 are details of the areas marked with corresponding numbers and arrows. (T = tympanum, PR = promontory A = remnants of annulus membranae tympanicus) H—E.

Fig 81 An area in Fig 80. The left margin of the figure coincides with the inferior annular remnant. The squamous epithelium (SQ) had prickles and superficial keratin-positive material but there is no granular cell layer Tympanally (right) the squamous epithelium continues, showing a decrease in degree of metaplasia. The basement membrane area is prominent. Subepithelially there is a pouch (T) connected with the middle ear space and lined by respiratory epithelium H—E 160 ×.

epithelium (independent metaplasia). In this squamous epithelium (Fig. 86) the basal cells formed a distinct layer of their own. Prickle cells were seen, the stratum granulosum was absent, and pseudoparakeratosis was seen over a small area. This squamous epithelium (Fig. 87) was inferiorly connected to the ear canal epidermis by slightly metaplastic epithelium. The connection, however was so narrow and the connecting metaplastic epithelium of such a low grade that the squamous epithelium on the promontory is likely to be of independent metaplastic origin.

The posterior tympanic floor and almost all the posterior tympanum were lined by a higher columnar epithelium which had undergone a mucous change. In the anterior tympanum the epithelium was ciliated and metaplastic, relatively thick, in the medial wall up to 10 cell layers (basal hyperplasia) Anteriorly to the perforation level a medial, a lateral and an inferior area of metaplasia could be distinguished. Posteriorly these areas united and at the level of the anterior edge of the annulus, they formed an unbroken lining that covered the lowest two-thirds of the lateral wall, the tympanic floor and the entire medial wall. The metaplasia was most pronounced medially and least pronounced in the floor where it began to weaken from the anterior tympanum backward. At the level of the posterior part of the promontory the metaplastic epithelium changed into columnar mucous epithelium. The epithelium of the epitympanum was less continuous, partly mucously changed and columnar and in the posterior parts of the middle ear it became more eosinophil cuboidal, and 1—2 layered.

The respiratory type epithelium of the orifice of the Eustachian tube was extensively hyperplastic. Some goblet and secretory cells were seen. The tubotympanal unbroken ciliary carpet continued backwards as an infero-medial strip extending to the sinus tympani and as a second, considerably shorter strip to the infero-lateral parts of the tympanum.

The tympanic mucosa, which was heavily thickened throughout, was hyperaemic and oedematous Only in the centre of the promontorial area and in the region of the lower perforation edge was it more fibrotic. Mainly subepithelially there was extensive, essentially lymphocytic infiltration. The malleus handle, the long process of incus, and the superstructure of the stapes were absent (Fig. 80).

No keratin-positive cells were found in the squamous epithelium of the promontory The tendency to keratinization of the squamous epithelium at the postero-inferior edge of the perforation, disclosed by the H E staining, was also confirmed by keratin stainings.

The tympanic epithelium stained well with both AB and PAS methods. The metaplastic epithelium, and the squamous epithelium of the perforation edges and the promontory stained with PAS, especially in their upper parts. AB staining, on the other hand, produced a slight positive response only in the area of the slightly metaplastic epithelium.

4 11 TEMPORAL BONE 11

The patient, at 83 had died in a chest hospital of acute respiratory infection complicating bilateral bronchiectatic disease. His hearing had been poor since childhood and the ears had shown intermittent discharge. Otoscopically the right ear showed total marginal

Fig 86 An area in Fig. 80, down from the Fig 85 area. Pseudoparakeratotic squamous epithelium is visible on the promontorial surface. Its stratum basale is distinct, stratum granulosum absent, but prickles can be discerned. H—E 400 x

Fig 87 An area also seen in Fig 80, down from the Fig 86 area. The pseudoparakeratotic squamous epithelium changes into less markedly metaplastic epithelium. H—E 160 x.

epithelium (independent metaplasia). In this squamous epithelium (Fig. 86) the basal cells formed a distinct layer of their own. Prickle cells were seen, the stratum granulosum was absent, and pseudoparakeratosis was seen over a small area. This squamous epithelium (Fig. 87) was inferiorly connected to the ear canal epidermis by slightly metaplastic epithelium. The connection, however was so narrow and the connecting metaplastic epithelium of such a low grade that the squamous epithelium on the promontory is likely to be of independent metaplastic origin.

The posterior tympanic floor and almost all the posterior tympanum were lined by a higher columnar epithelium which had undergone a mucous change. In the anterior tympanum the epithelium was ciliated and metaplastic, relatively thick, in the medial wall up to 10 cell layers (basal hyperplasia). Anteriorly to the perforation level, a medial a lateral and an inferior area of metaplasia could be distinguished. Posteriorly these areas united and at the level of the anterior edge of the annulus, they formed an unbroken lining that covered the lowest two-thirds of the lateral wall, the tympanic floor and the entire medial wall. The metaplasia was most pronounced medially and least pronounced in the floor where it began to weaken from the anterior tympanum backward. At the level of the posterior part of the promontory the metaplastic epithelium changed into columnar mucous epithelium. The epithelium of the epitympanum was less continuous, partly mucously changed and columnar and in the posterior parts of the middle ear it became more eosinophil, cuboidal, and 1—2 layered.

The respiratory-type epithelium of the orifice of the Eustachian tube was extensively hyperplastic. Some goblet and secretory cells were seen. The tubotympanal, unbroken ciliary carpet continued backwards as an infero-medial strip extending to the sinus tympani and as a second, considerably shorter strip to the infero-lateral parts of the tympanum.

The tympanic mucosa, which was heavily thickened throughout, was hyperaemic and oedematous. Only in the centre of the promontorial area and in the region of the lower perforation edge was it more fibrotic. Mainly subepithelially there was extensive, essentially lymphocytic infiltration. The malleus handle, the long process of incus, and the superstructure of the stapes were absent (Fig. 80)

No keratin-positive cells were found in the squamous epithelium of the promontory. The tendency to keratinization of the squamous epithelium at the postero-inferior edge of the perforation, disclosed by the H E staining, was also confirmed by keratin stainings.

The tympanic epithelium stained well with both AB and PAS methods. The metaplastic epithelium, and the squamous epithelium of the perforation edges and the promontory stained with PAS, especially in their upper parts. AB staining, on the other hand, produced a slight positive response only in the area of the slightly metaplastic epithelium.

4.11 TEMPORAL BONE 11

The patient, at 83 had died in a chest hospital of acute respiratory infection complicating bilateral bronchiectatic disease. His hearing had been poor since childhood and the ears had shown intermittent discharge. Otoscopically the right ear showed total marginal

Fig 87 A area also seen in Fig 80, down from the Fig 86 area. The pseudoparakeratotic squamous epithelium changes into less markedly metaplastic epithelium. H—E 160 x.

epithelium (independent metaplasia) In this squamous epithelium (Fig 86) the basal cells formed a distinct layer of their own. Prickle cells were seen, the stratum granulosum was absent, and pseudoparakeratosis was seen over a small area. This squamous epithelium (Fig 87) was inferiorly connected to the ear canal epidermis by slightly metaplastic epithelium. The connection, however was so narrow and the connecting metaplastic epithelium of such a low grade that the squamous epithelium on the promontory is likely to be of independent metaplastic origin.

The posterior tympanic floor and almost all the posterior tympanum were lined by a higher columnar epithelium which had undergone a mucous change. In the anterior tympanum the epithelium was ciliated and metaplastic, relatively thick, in the medial wall up to 10 cell layers (basal hyperplasia) Anteriorly to the perforation level, a medial, a lateral and an inferior area of metaplasia could be distinguished. Posteriorly these areas united and at the level of the anterior edge of the annulus, they formed an unbroken lining that covered the lowest two-thirds of the lateral wall, the tympanic floor and the entire medial wall. The metaplasia was most pronounced medially and least pronounced in the floor where it began to weaken from the anterior tympanum backward. At the level of the posterior part of the promontory the metaplastic epithelium changed into columnar mucous epithelium. The epithelium of the epitympanum was less continuous, partly mucously changed and columnar and in the posterior parts of the middle ear it became more eosinophil, cuboidal, and 1—2 layered.

The respiratory-type epithelium of the orifice of the Eustachian tube was extensively hyperplastic. Some goblet and secretory cells were seen The tubotympanal, unbroken ciliary carpet continued backwards as an infero-medial strip extending to the sinus tympani and as a second, considerably shorter strip to the infero-lateral parts of the tympanum.

The tympanic mucosa, which was heavily thickened throughout, was hyperaemic and oedematous. Only in the centre of the promontorial area and in the region of the lower perforation edge was it more fibrotic. Mainly subepithelially there was extensive, essentially lymphocytic infiltration. The malleus handle, the long process of incus, and the superstructure of the stapes were absent (Fig 80).

No keratin-positive cells were found in the squamous epithelium of the promontory The tendency to keratinization of the squamous epithelium at the postero-inferior edge of the perforation, disclosed by the H E staining, was also confirmed by keratin stainings.

The tympanic epithelium stained well with both AB and PAS methods. The metaplastic epithelium, and the squamous epithelium of the perforation edges and the promontory stained with PAS, especially in their upper parts. AB staining, on the other hand, produced a slight positive response only in the area of the slightly metaplastic epithelium

perforation of the pars tensa. The middle ear was moist but the ear canal had no noticeable discharge.

4.11.1 *Histology*

Inferiorly a tiny fibrous annulus remained, and the ear canal epidermis grew smoothly over it on the hypotympanic mucosa and continued, tapering, medially (Figs. 88, 96, 97). Both posteriorly and anteriorly to this area the squamous ear canal epithelium immigrated less extensively into the hypotympanum, but always for a distance of at least 0.5 mm. At the anterior and superior edge of the perforation the squamous epithelium showed a tendency to penetrate the inflamed tissue to the epitympanic space where a keratinizing squamous epithelium was seen to grow for a distance of 0.5 mm on the epitympanal mucosa (Figs. 90, 91). At the superior edge the squamous epithelium grew along the adhesion bridges over the remaining parts of the ossicles towards the medial wall of the middle ear. In certain areas the *propria* under the squamous epithelium was thin and fibrotic, in others it was oedematous and loose, infiltrated by inflammatory cells and, especially anteriorly by numerous gland-like structures and cysts (Fig. 95).

Generally keratinizing squamous epithelium changed into columnar or ciliated columnar epithelium for a very short distance (Figs. 89, 98—100), sometimes through a metaplastic transitional area (Fig. 97). In some places in the hypotympanum the squamous epithelium tended to grow beneath the columnar epithelium for a short distance, pushing it aside (Figs. 98, 100). The granular cell layer and the superficial keratin followed the squamous epithelium close to the point of epithelial junction. In the hypotympanic area, a parakeratotic desquamation was sometimes seen.

In the tympanum, the squamous epithelium was always smooth and showed no papillary growth. The main part of the promontorial epithelium was metaplastic, and lacked the granular cell and keratin layers (Fig. 94). On the posterior promontory this metaplasia surrounded an area of squamous epithelium 1.8 mm high and 0.8 mm wide (Fig. 92) connected with a very narrow squamous strip to immigrating ear canal epithelium. This independent promontorial squamous epithelium showed prickles and some granular cells. The cell layers, however were not yet distinctly arranged and some pseudoparakeratotic desquamating strips could be seen on top of the epithelium.

An isolated area of squamous epithelium was found in the *sinus tympani*, which was otherwise covered by the columnar type of epithelium (Figs. 88, 93). This squamous epithelium showed basal, prickle, and granular cell layers. There was *no superficial* keratin but some of the external cells were seen loose in the lumen in a parakeratotic fashion.

Generally the tympanic mucosa was very hyperplastic, fairly hyperaemic and infiltrated by chronic inflammatory cells. The carious ossicular chain was surrounded and fixed by fibrotic tissue. The head of the malleus showed a bony union to the roof of the epitympanum.

In the anterior part of the tympanum the columnar epithelium contained large ciliated areas which decreased in number posteriorly. *However in the lower tympanum, ciliated narrow strips continued to the most infero-*posterior parts. Also some areas of the medial wall and the superior portion of the tympanum showed ciliated cells.

The orifice of the Eustachian tube showed a thick mucosa which was oedematous and infiltrated with inflammatory cells. The tubal epithelium was ciliated columnar with stratified and pseudostratified arrangement of cells.

The immigrating squamous epithelium gave a positive response to keratin staining whereas the metaplastic and the promontorial columnar epithelium were negative.

Fig 99 The upper perforation edg corresponding to Fig 98, 0.6 mm anteriorly The stratum granulosum of the immigrating, partly parakerototic ep dermis is very prominent. The epithelial junction is abrupt (arrow) H—E 160 x.

perforation of the pars tensa. The middle ear was moist but the ear canal had no noticeable discharge.

4.1.1 *Histology*

Inferiorly a tiny fibrous annulus remained, and the ear canal epidermis grew smoothly over it on the hypotympanic mucosa and continued, tapering medially (Figs. 88 96, 97). Both posteriorly and anteriorly to this area the squamous ear canal epithelium immigrated less extensively into the hypotympanum, but always for a distance of at least 0.5 mm. At the anterior and superior edge of the perforation the squamous epithelium showed a tendency to penetrate the inflamed tissue to the epitympanic space where a keratinizing squamous epithelium was seen to grow for a distance of 0.5 mm on the epitympanal mucosa (Figs. 90, 91). At the superior edge the squamous epithelium grew along the adhesion bridges over the remaining parts of the ossicles towards the medial wall of the middle ear. In certain areas the propria under the squamous epithelium was thin and fibrotic, in others it was oedematous and loose, infiltrated by inflammatory cells and, especially anteriorly by numerous gland-like structures and cysts (Fig. 95).

Generally keratinizing squamous epithelium changed into columnar or ciliated columnar epithelium for a very short distance (Figs. 89 98—100) *sometimes* through a metaplastic transitional area (Fig. 97). In some places in the hypotympanum the squamous epithelium tended to grow beneath the columnar epithelium for a short distance, pushing it aside (Figs. 98 100). The granular cell layer and the superficial keratin followed the squamous epithelium close to the point of epithelial junction. In the hypotympanic area, a parakeratotic desquamation was sometimes seen.

In the tympanum, the squamous epithelium was always smooth and showed no papillary growth. The main part of the promontorial epithelium was metaplastic, and lacked the granular cell and keratin layers (Fig. 94). On the posterior promontory this metaplasia surrounded an area of squamous epithelium 1.8 mm high and 0.8 mm wide (Fig. 92) connected with a very narrow squamous strip to immigrating ear canal epithelium. This independent promontorial squamous epithelium showed prickles and some granular cells. The cell layers, however were not yet distinctly arranged and some pseudoparakeratotic desquamating strips could be seen on top of the epithelium.

An isolated area of squamous epithelium was found in the sinus tympani, which was otherwise covered by the columnar type of epithelium (Figs. 88, 93). This squamous epithelium showed basal, prickle, and granular cell layers. There was no superficial keratin but some of the external cells were seen loose in the lumen in a parakeratotic fashion.

Generally the tympanic mucosa was very hyperplastic, fairly hyperaemic and infiltrated by chronic inflammatory cells. The cariotic ossicular chain was surrounded and fixed by fibrotic tissue. The head of the malleus showed a bony union to the roof of the epitympanum.

In the anterior part of the tympanum the columnar epithelium contained large ciliated areas which decreased in number posteriorly. However in the lower tympanum ciliated narrow strips continued to the most inferoposterior parts. Also some areas of the medial wall and the superior portion of the tympanum showed ciliated cells.

The orifice of the Eustachian tube showed a thick mucosa which was oedematous and infiltrated with inflammatory cells. The tubal epithelium was ciliated columnar with stratified and pseudostratified arrangement of cells.

The immigrating squamous epithelium gave a positive response to keratin stainings whereas the metaplastic and the promontorial squamous epithelium were negative.

Tubal and tympanal epithelium was AB and PAS-positive. Tympanally medial metaplastic epithelium also stained with both methods, whereas the squamous epithelium was AB negative and very faintly PAS-positive

4 12 TEMPORAL BONE 12

The patient's medical history is given under Temporal Bone 11 Otoscopy revealed a total marginal perforation of the left pars tensa There was purulent discharge in the ear canal

4 12 1 *Histology*

The drum membrane showed a large perforation which comprised the whole pars tensa and the anterior part of Shrapnell's membrane. The epidermis of the ear canal immigrated both inferiorly and superiorly (Figs. 101—103) onto the middle ear forming at the posterior promontory a relatively strongly keratinizing unbroken lining of squamous epithelium This lining continued about 1 mm backward The sinus tympani was free from squamous epithelium and was covered by metaplastic and ciliated columnar epithelium Hypotympanally the epidermal immigration gradually withdrew in a lateral direction extending in the posterior part of the perforation only to the area of the annular remnant Towards the antero-inferior edge of the perforation the change was similar On the other hand the superior squamous epithelial immigration which began from the anterior part of the perforation and at the oval window level extended along the bridge formed through the ossicular chain to line the medial wall retained its dimension in the following sections (backward) and joined the inferior epidermal ingrowth at the level described at the beginning of this chapter Anteriorly of the long process of the incus, the connective tissue bridge was interrupted by a short air space in the medial part of the epitympanum The fairly strongly keratinizing squamous epithelium also immigrated to this air space and lined its lower part, and after a short slightly metaplastic transitional area it changed abruptly into cuboidal epithelium of 1—3 layers (Fig 104)

No appreciable squamous epithelial immigration was noted in the anterior and posterior perforation edge

At some places of the perforation edges, the squamous epithelium sent projections (Figs. 105—107) into the subepithelial connective tissue. The tendency to depth growth was particularly evident medially of the upper edge of the perforation where it was epitympanally directed (Figs. 105 106) In addition a few small subepithelial keratin cysts could be seen in the medial tympanal wall under the immigrated epidermis.

In general the epidermal junctions with other epithelium were fairly sharp often strongly keratinizing epidermis extended with all its layers right up to the line of junction and was transformed through a weak metaplastic phase of varying length into cuboidal or columnar epithelium In places the immigrating epidermis lost its keratin and granular layer a few tenths of millimetres before the junction It was

Fig 101 General view of the tympanum. Inferiorly the squamous epithelium immigrates directly into the hypotympanum (nothing is left of the perforation edge), superiorly the immigration takes place along a bridge formed by the carious auditory ossicles. The head of the malleus shows bony union to the epitympanic roof. Above the cholesterol cyst (CC), in the lower part of the epitympanal cavity there is an area of hyperkeratotic epidermis (arrow). H—E.

Fig 102 The hypotympanal squamo-columnar junction in Fig 101 (arrow 102). At the abrupt junction line the partly parakeratotic epidermis thickens and its granular cell and keratin layers are very pronounced. Beyond the transition zone of some 0.2 mm (between arrows) the epithelium is respiratory and showed also ciliary coating in the right margin of the figure. *H—E 160*

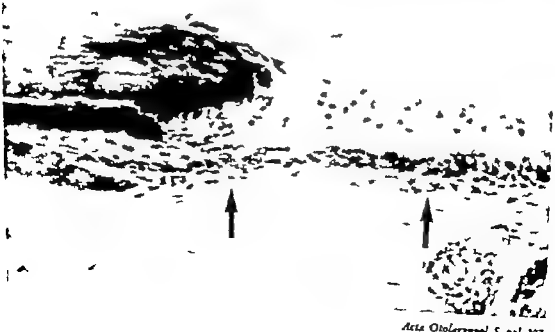

Fig 103 The squamo-columnar junction on the tympanal side of the upper perforation edge (2.9 mm anteriorly to the level of Fig 101) The epidermis is abruptly changed into columnar epithel um of atery appearance and is soon covered by cilia. H—E 160 x

Fig 104 Medial wall f the tympanum in the oval w dow area. The immigrat ng aggressive looking epidermis keratinizes abundantly (K = kerati) and stratum gran losum is prominent. *The epithelial* junction is abrupt (rrow). H—E 160 x.

Fig. 105. General view 1.9 mm anteriorly to Fig. 101. A nearly total epidermization (= epidermal covering) is seen, being absent only from the oval window (FO) area. The epidermis shows a tendency to depth growth towards the attic (arrow) superiorly and at the perforation level area (arrow) inferiorly. A cholesterol cyst (CC) is seen in the oval window area. (A = anular level.) H—E.

4.13 TEMPORAL BONE 13

This patient had died at the age of 58 of bronchial carcinoma with extensive metastases. Otoscopy of his left ear drum revealed a nearly total marginal perforation. The ear contained some purulent exudate.

4.13.1 *Histology*

The pars tensa of the drum membrane was totally absent. Shrapnell's membrane was replaced by connective tissue obliteration, forming a bridge from the level of the ear canal roof through the ossicular remnants to the oval window area. At the level of the anterior promontory the obliteration completely blocked the connection up- and forward from the mesotympanum (Fig. 108). The malleus handle was missing.

The epidermis of the ear canal completely lined the anterior part of the tympanic cavity. The promontory also was totally epidermized. Posteriorly the keratinizing squamous epithelium gradually began to disappear beginning at the posterior oval window area. The floor of the tympanum, however was almost completely lined by epidermis. In the posterior parts of the perforation the epidermal immigration was considerably slighter and extended only a short distance onto the tympanic side. In the junctional areas, 0.1—0.5 mm before the epidermis ended it was seen to lose the keratin cover the stratum granulosum and gradually also the stratum spinosum, and through a parakeratotic (and a pseudoparakeratotic) phase it was transformed into metaplastic and gradually into columnar epithelium (Figs. 109, 110). The total width of the area of transformations varied, but was usually of the order of 1—2 mm. At some places in the area the epithelium was low of a clearly squamous type non-keratinizing and —3 layers thick.

All epidermal cell layers could be distinguished in the normally keratinizing squamous epithelium of the middle ear (Figs. 111, 112). Extensive perinuclear vacuolization was typical (Fig. 109) apart from the most basal cell layers. Furthermore, the epidermal papillary structure was absent from the tympanic side. Moderate keratin film, seen throughout on the squamous epithelium, nowhere formed an accumulation suggestive of incipient cholesteatoma. Nor was any subepithelial growth of the tympanic squamous epithelium noted.

The mucosa, free from squamous epithelium, of the postero-medial wall of the tympanum, sinus tympani and the postero-medial side of the luminal roof was lined by columnar epithelium which was partly detached. No cilia were seen. Profuse infiltration of inflammatory cells and strong hyperaemia in the subepithelial connective tissue were observed in these areas. At the junctions towards the squamous epithelium this stroma, which throughout the middle ear was strongly thickened, became poor in cells, denser and less vascularized. In the pouches the mucosa was looser and cysts and pseudocysts were visible.

The epithelium of the Eustachian tube was of the respiratory type, and in some places hyperplastic. Cilia lined its surface throughout (Fig. 114). The tubal lumen opened into the anterior tympanum after which, posteriorly the cavity diminished and ended blindly. In the anterior tympanum, the epithelium, mainly superiorly and inferiorly changed from respiratory into cuboidal (Fig. 113), partly also losing its ciliary lining. Laterally a strip of cilia continued to the postero-lateral angle of the cavity. The anterior tympanum and especially the tube contained goblet cells and large numbers of secretory columnar cells.

Keratin stainings confirmed the epidermal keratinizing character of the squamous epithelium of the middle ear (Fig. 112).

In mucus stainings the superficial parts of the tympanic squamous epithelium were faintly positive to PAS but not at all to AB.

typical of the junctional areas, however that the borderline was very sharp and an epidermis of aggressive appearance often "clashed with a remarkably delicate type of epithelial cells

Posteriorly the promontory was lined by strongly keratinizing squamous epithelium Anteriorly the medial wall epithelium was metaplastic (disorganized, multilayered non squamous) and the frontal part was even ciliated with basal hyperplasia. Considerable amounts of keratin were seen on the surface of all squamous epithelium with an uninterrupted connection with the ear canal Only in the lower part of the epitympanal cavity was there some keratin collection on the squamous epithelium suggesting incipient cholesteatoma.

In the posterior tympanum the epithelium was uncontinuous and of columnar and cuboidal type, with occasional cilia on its surface. In the anterior tympanal area it was also uncontinuous stratified and partly lined by cilia. The watery appearance was typical of this modified respiratory epithelium and this made the exact evaluation of the epithelium difficult.

Already anteriorly the luminal roof and the medial wall showed changes suggestive of early epithelial metaplasia. In the anterior tympanum the roof first lost the ciliation which continued posteriorly as medial and supero-lateral tapering strips for some 2 mm The markedly broad inferior track of ciliated cells continued on the tympanic floor and further infero-medially to the posterior parts of the tympanum At the level of the windows the strip was interrupted by the zone of squamous epithelium described above

The epithelium of the Eustachian tube was respiratory somewhat hyperplastic and remarkably watery It was lined by cilia throughout only at the tubal orifice the roof epithelium had no cilia.

The tympanic mucosa especially in the anterior parts and the pouches, was heavily thickened and oedematous There were numerous cysts and pseudocysts, and some gland like structures, mainly in the medial wall of the tympanum (Fig 105) Polypotic granulation formation was seen in the antero-inferior part of the medial wall Generally the promontorial mucosa, especially in the posterior parts, was more fibrotic and less infiltrated by inflammatory cells. A cholesterol cyst was seen in the upper part of the oval window area, between the facial canal and the incudostapedial joint. The malleus handle was missing and its cariotic head showed a bony union to the roof of the epitympanum (Fig 101)

The tympanic squamous epithelium showed strong keratin staining The granular cell layer stained with both the Baker and the Ladewig method giving a pronounced dark and red line, respectively in which individual granules of varying size could be discerned only here and there Keratin staining seemed more pronounced on the tympanic than the ear canal side

The columnar cuboidal secretory and mucously changed epithelium of the Eustachian tube and tympanum stained with AB and more markedly with PAS The tympanic squamous epithelium stained faintly with PAS, mainly in its superficial parts. This epithelium as well as the area of marked metaplasia, were AB negative,

Fig. 109. The junction of the superior squamous immigration in Fig. 108 (arrow 109). The basal epithelial layers are hyperplastic and perinuclear vacuolization is seen more superficially. Stratum granulosum ends (arrow), and there is no keratin film. The fibrotic subepithelium becomes looser and is infiltrated abundantly by round cells on reaching the area of columnar epithelium. H—E 160

Fig. 110. The junction of the inferior squamous immigration (on the upper promontory surface) in Fig. 108 (arrow 110). The epidermis is seen to lose the granular cells after a parakeratotic phase (Pa) and to change through pseudoparakeratosis (Ps) into squamous epithelium of metaplastic type (M), and further into columnar epithelium (R). The basement membrane area is distinctly seen under the squamous epithelium. A stromal ... begins in the junctional ... and becomes pronounced towards and under the columnar ... The width of the area covered by Fig. 110 is less than 1.0 mm. H—E 160 x.

5 DISCUSSION

5 1 POSTMORTEM CHANGES AND ARTIFACTS

Hentzer (1969) after fixation more than three hours post mortem found autolytic structural damage in the cell organelles, e g the cilia In his study (1970) of normal middle ear mucosa, he therefore used immediate post mortem fixation He also omitted the decalcification and he attributed the remarkably extensive tympanic ciliation to the better preserving power of this technique. Sadé (1966 a) when he described the extensive ciliary lining of the middle ear characteristic of the true mucosa used immediate postmortem fixation and a short decalcification period. In their light and electron microscopic studies Lim et al (1967) Kawabata & Paparella (1969) Lim & Hussl (1969) Hussl & Lim (1969 a, b) and Lim (1970) also used techniques omitting decalcification As pointed out by Hentzer (1970) it is evident that both a too late postmortem fixation and the long term decalcification with strong acids, which have been used earlier damaged the epithelial lining and especially the cilia, leading to misinterpretations. Differences in interpretation can also be attributed to improved staining methods and increased interest in the mucociliary system and the mechanism of secretory otitis.

Since postmortem autolytic changes begin in the first few hours after death it is obvious that such changes are present in ears which have been stored for an average of 58 hours, although cold storage prevents pronounced autolysis. The relatively long period of decalcification (6—8 weeks) also affects the architecture of epithelial cells. Despite the fact that including intermediate storages, it took 3—11 months before the sections were completed the distortions of cell and tissue structure were slight and did not hamper the microscopic analysis With the present method the cilia were well preserved, and appeared as an almost unbroken carpet in the Eustachian tubes of all ears. Nor could any correlation be noted between the preservation on the tympanal cilia and the various durations (13—91 hours) of the pre-fixation cold storage periods. Since the cilia are structures very sensitive to damage, it can be assumed that autolysis and possible preparation artifacts play no remarkable role in the present work

5 2 VALIDITY OF STAININGS

In addition to the H E staining for general characteristics, PAS and AB stains were used mainly to give information on the epithelial secretory function and mucin composition Since the diastase digestion in PAS staining was not used the polysaccharides (e.g glycogen) if present also gave a positive reaction

In the normal epidermis, phospholipids are found in the granular cell layer where the epithelial cells begin to keratinize The quality of the resulting keratin depends on the degree of hydrolysis of the transitional zone as hydrolytic enzymes are liberated from lysosomes (Jarrett & Spearman 1967) Phospholipids rich in energy are formed at the time of nuclear breakdown and their energy is needed when polypeptide chains are resynthetized and polymerized into a keratin molecule (Jarrett et al 1959) The phospholipid content of the horny layer indicates the

degree of autolysis of the transitional zone: if the autolysis is effective, phospholipids are seen in the transitional zone only but if the hydrolysis is defective the whole cell including the nucleus, travels into the horny layer which is then positively stained for phospholipids (Jarrett et al 1965)

The turquoise-bluish colour imparted by Luxol Fast Blue to keratinizing areas was often relatively faint, but the morphology of the epithelial cells was clearly visualized with this staining

Baker's method stained the phospholipid positive areas blue-black throughout, and was the best and most informative of the keratin staining methods used. In addition to the phospholipoproteins, also e.g. the nucleoproteins stain with Baker's method. For this reason, only negative Baker staining after phospholipid extraction confirms the (phospholipid-) specificity of this staining method. Extraction can be carried out e.g. by lipase digestion with pyridine extraction, the results are uncertain (T Palva et al 1972) Since formalin fixation makes the phospholipoprotein complex resistant to the lipase effect, digestion should have been carried out on fresh unfixed sections. With the present study plan, this was impossible. The corresponding controls have been carried out on frozen sections (T Palva et al., 1972) and they showed that positive epidermal staining was due to phospholipids.

The Ayoub-Shklar modification of Mallory's staining usually stained the whole epithelium red, and the keratin selectivity claimed by Shklar (1968) was not visible in the formalin-fixed sections. For this reason this staining was replaced with Ladewig's modification, which stained the keratin layer and granules an intense reddish violet. T Palva et al. (1972) assumed that a fixation artifact was involved here also, for no similar staining could be verified in unfixed frozen section staining.

The keratin stainings together supplied so much information of keratinization that tympanic keratinization process findings seen on H E staining, and confirmed by the keratin stainings used, can be considered reliable.

5.3 PATHOLOGY OF THE TYMPANUM AND TYMPANIC MEMBRANE

(See also Table I on pp 86,87)

5.3.1 *Types of perforation*

The present material contained seven central perforations of the pars tensa two were partly marginal (= subtotal) and four total. In ears with total perforation of the pars tensa, the epitympanum was extensively obliterated by connective tissue and the pars flaccida was replaced by thick fibrotic obliteration in the region of the auditory ossicles. In three of these ears (Temporal Bones 11—13) a bridge developed, running along the ossicular chain to the medial wall of the middle ear However none of the four showed the typical attic perforation, nor were there any signs of epitympanal lateral bone erosion. The handle of the malleus had in all four cases been destroyed.

Of the perforations of the present material, one was dry (Temporal Bone 9), three were moist (Temporal Bones 6, 10, 11), and the remaining nine were suppurative.

The absence of attic perforation and cholesteatoma in the present material deserves special attention (one ear Temporal Bone 12 showed however "aggressive" hyperkeratosis). A total of 900 ears were inspected to collect the present material and, if the four ears with adhesive processes not included in the material are taken into account, the number of chronic middle ear processes found was 17 (1 9 per cent). There were also three ears which had been treated with radical mastoidectomy and when they are included the incidence rises to 2.2 per cent. On school age material, Ostman (1902) quoted an incidence of 1.6, Lergard (1923) 1 4 and Marland (1918) 6 9 per cent. Bezold (1891) found

5 DISCUSSION

5 1 POSTMORTEM CHANGES AND ARTIFACTS

Hentzer (1969) after fixation more than three hours post mortem found autolytic structural damage in the cell organelles, e g the cilia In his study (1970) of normal middle ear mucosa, he therefore used immediate post mortem fixation He also omitted the decalcification and he attributed the remarkably extensive tympanic ciliation to the better preserving power of this technique. Sadé (1966 a) when he described the extensive ciliary lining of the middle ear characteristic of the true mucosa, used immediate postmortem fixation and a short decalcification period. In their light and electron microscopic studies Lim et al (1967) Kawabata & Paparella (1969) Lim & Hussl (1969) Hussl & Lim (1969 a, b) and Lim (1970) also used techniques omitting decalcification As pointed out by Hentzer (1970) *it is evident that* both a too late postmortem fixation and the long term decalcification with strong acids, which have been used earlier damaged the epithelial lining and especially the cilia leading to misinterpretations Differences in interpretation can also be attributed to improved staining methods and increased interest in the mucociliary system and the mechanism of secretory otitis

Since postmortem autolytic changes begin in the first few hours after death it is obvious that such changes are present in ears which have been stored for an average of 58 hours, although cold storage prevents pronounced autolysis The relatively long period of decalcification (6—8 weeks) also affects the architecture of epithelial cells Despite the fact that, including intermediate storages, it took 3—11 months before the sections were completed the distortions of cell and tissue structure were slight and did not hamper the microscopic analysis. With the present method the cilia were well preserved, and appeared as an almost unbroken carpet in the Eustachian tubes of all ears. Nor could any correlation be noted between the preservation on the tympanal cilia and the various durations (13—91 hours) of the pre-fixation cold storage periods. Since the cilia are structures very sensitive to damage, it can be assumed that autolysis and possible preparation artifacts play no remarkable role in the present work

5 2 VALIDITY OF STAININGS

In addition to the H E staining for general characteristics, PAS and AB stains were used mainly to give information on the epithelial secretory function and mucin composition Since the diastase digestion in PAS staining was not used the polysaccharides (e.g glycogen) if present, also gave a positive reaction

In the normal epidermis, phospholipids are found in the granular cell layer where the epithelial cells begin to keratinize. The quality of the resulting keratin depends on the degree of hydrolysis of the transitional zone as hydrolytic enzymes are liberated from lysosomes (Jarrett & Spearman 1967) Phospholipids rich in energy are formed at the time of nuclear breakdown and their energy is needed when polypeptide chains are resynthetized and polymerized into a keratin molecule (Jarrett et al 1959) The phospholipid content of the horny layer indicates the

cuboidal and even flat epithelium of a few ears.

The ciliated columnar epithelium of an active hyperplastic mucosa was occasionally up to 5—10 cell layers thick. Cuboidal and flat epithelium appeared more often on the fibrotic mucous membranes, free from inflammatory cells e.g. in Temporal Bone 9 the cuboidal and flat, even endothelium-like epithelium predominated. These findings support the view that inflammation stimulus produces epithelial hypertrophy (Ojala, 1950) and, especially in chronic infections, hyperplasia and metaplasia (Zechner 1965). According to Friedmann (1959), chronic inflammation causes the reversal of flat epithelium to respiratory type. After inflammation and trophic hyperaemia have disappeared, atrophy again resulting in flat type epithelium takes place (Ojala, 1950).

5.3.3.2. Mucous epithelium and secretory components

The amount of epithelium showing varying degree of mucous change was considerable in about half of the ears. It was most abundant in Temporal Bones 7 and 8 which showed extensive epithelial areas composed almost solely of goblet cells.

In addition to the goblet cells, also columnar and cuboidal secretory cells were seen. Even some ciliated cells showed PAS- and AB-positive material which may suggest a possible secretory function (Sadé, 1966 a). The apical parts of the epithelial cells reacted best to mucus stainings. Glands were noted in six ears, the largest numbers in Temporal Bones 11 and 12. Cysts were visible in all. Both the glandular and the cystic secretion was AB- and PAS-positive. The secretory (mainly goblet) cells were absent from three ears, but even in them, apart from Temporal Bone 9 the epithelium in some places showed PAS-positive and, more faintly AB-positive staining. In Temporal Bone 9 only a few cystic cavities stained PAS- and AB-positively.

It is generally accepted that hyperplastic transformation (Sadé, 1966 b) and increased secretory function of the epithelium (Wittmaack, 1918 Beck, 1926 Singer 1933 Friedmann, 1956 Bendek, 1963 T Palva et al., 1964 Zechner 1965) result from chronic inflammation. But it is not clear whether in this connection a basal cell on differentiation becomes a secretory and not a ciliated cell (Rhodin, 1959), or whether a ciliated cell undergoes metaplasia into a goblet cell (Spoendlin, 1959). The former mechanism has had more supporters (Latta & Schall, 1934 Lim et al., 1967). In secretory otitis, Lim & Birck (1971) found electron microscopically ciliogenesis in some cells containing secretory granules. This might indicate that the cells were adapting themselves to the transport needs increased by secretory otitis. Since in secretory otitis the epithelium shows a hyperplastic transformation, a proliferation rather than a metaplasia (Lim & Birck, 1971), it does not seem meaningful for a secretory cell population to develop through a highly specialized ciliary cell phase engaged in transport function. It is more probable that the secretory cells differentiate and proliferate directly from the basal cells. The fact that some young ciliating cells show secretory granules is no direct evidence against the above mechanism. Nor can far reaching conclusions be drawn on the basis of the electron microscopic architecture of a few cells. On the other hand, if a certain differentiation of the basal cell begins in a phase of profuse proliferation it may remain partial, and result in the above intermediate forms. The AB- and PAS-positivity of some ciliated cells also may instead of secretory function, indicate an active carbohydrate metabolism of the ciliated cells, e.g. PAS-positivity (without diastase) may show glycogen (as a source of cell energy). The possibility of artifacts and the *partial differentiation*, mentioned above, also must be taken into consideration in

a cholesteatoma and/or perforation of Shrapnell s membrane in 14 6 per cent of his cases of chronic otitis Accordingly the present material should have contained three cases of this type Considering that Scheibe (1917) found a cholesteatoma in 91 and Simpson (1954) in 94 per cent of their cases of chronic otitis with epitympanal perforation, it may be assumed that treatment has been sought earlier for ears with cholesteatomatous and at the same time, often attical processes. In fact, three operated cases were included in the present total material

5.3.2 *Mucosal quality*

The tympanic mucosa in all the cases was thickened to a varying extent. Not only mucosal hyperplasia of varying degree but in places also very pronounced oedema, and in some cases marked organization, fibrosis and even tympanosclerosis (Temporal Bone 9) was seen. Granulation processes of different degrees were noted. There were varying numbers of cysts and pseudocysts, and glands were seen in six ears they usually stained positively both with AB and PAS Vascularization varied, but was usually abundant.

In 12 temporal bones the tympanal mucosa was infiltrated by inflammatory cells to a varying extent The predominant types of cells were lymphocytes and plasma cells. Polymorphonuclear cells were also seen in a few ears Varying numbers of macrophages were observed. In Temporal Bone 9 the mucosa was the most fibrotic of the whole material and the active inflammatory process was over It was also the only completely dry ear of the material

The subepithelial round cell infiltration formed follicular accumulations in six ears (cf Goerke, 1905 Wittmaack, 1926 Singer 1933 T Palva et al 1964) One patient (Temporal Bones 11 12) had a history of tuberculosis in the lymph nodes of the neck, and another (Temporal Bones 8 10) had been treated in a chest hospital for pulmonary tuberculosis. The follicles however showed nothing suggestive of tuberculosis but apparently represented a mode of reaction typical of the middle ear mucosa in prolonged, chronic inflammation According to Singer (1933) inflammatory cell infiltration acts as the reticuloendothelial system of middle ear mucosa. These cell accumulations may participate in local antibody formation (Zechner 1966)

Squamo-columnar epithelial junctions, in particular were infiltrated by inflammatory cells only once (Temporal Bone 8) In three ears a few lymphocytes were seen under the squamous epithelium up to the junction but *from the junction onward their number* increased (Temporal Bones 11— 13) and even follicular formations appeared (Temporal Bones 11 12) This finding supported the general impression that the round cell infiltration underneath the squamous epithelium was somewhat less pronounced than under the columnar cuboidal or flat epithelium.

5 3.3 *Epithelium*

5.3.3 1 Columnar cuboidal and flat epithelium

Respiratory epithelium was very common in the middle ear Cilia were seen in all the cases, and they usually continued backward from the unbroken ciliary lining of the orifice of the Eustachian tube and antero-inferior tympanum as one to four tapering tracks. In most temporal bones they remained within the maximal extension limits defined by Sadé (1966 a) but sometimes exceeded them (Hentzer 1970) in the posterior tympanum and epitympanum and even in the region of mastoid air cells (T Palva et al., 1964) Cilia were also occasionally seen on the tympanic surface of the ear drum (e g Temporal Bone 6) In one ear (Temporal Bone 7) the myringitic ear drum was tympanally lined by ciliated columnar epithelium which everted onto its external side In addition to columnar epithelium cilia appeared at some places on the

cuboidal and even flat epithelium of a few ears.

The ciliated columnar epithelium of an active hyperplastic mucosa was occasionally up to 5—10 cell layers thick. Cuboidal and flat epithelium appeared more often on the fibrotic mucous membranes, free from inflammatory cells e.g. in Temporal Bone 9 the cuboidal and flat, even endothelium-like epithelium predominated. These findings support the view that inflammation stimulus produces epithelial hypertrophy (Ojala, 1950) and, especially in chronic infections, hyperplasia and metaplasia (Zechner 1965). According to Friedmann (1959), chronic inflammation causes the reversal of flat epithelium to respiratory type. After inflammation and trophic hyperaemia have disappeared, atrophy again resulting in flat-type epithelium takes place (Ojala, 1950)

5.3.3.2. Mucous epithelium and secretory components

The amount of epithelium showing varying degree of mucous change was considerable in about half of the ears. It was most abundant in Temporal Bones 7 and 8 which showed extensive epithelial areas composed almost solely of goblet cells.

In addition to the goblet cells, also columnar and cuboidal secretory cells were seen. Even some ciliated cells showed PAS- and AB-positive material which may suggest a possible secretory function (Sadé, 1966 a). The apical parts of the epithelial cells reacted best to mucus stainings. Glands were noted in six ears, the largest numbers in Temporal Bones 11 and 12. Cysts were visible in all. Both the glandular and the cystic secretion was AB- and PAS-positive. The secretory (mainly goblet) cells were absent from three ears, but even in them, apart from Temporal Bone 9 the epithelium in some places showed PAS-positive and, more faintly AB-positive staining. In Temporal Bone 9 only a few cystic cavities stained PAS- and AB-positively

It is generally accepted that hyperplastic transformation (Sadé, 1966 b) and increased secretory function of the epithelium (Wittmaack, 1918 Beck, 1926 Singer 1933 Friedmann, 1956 Bendek, 1963 T Palva et al., 1964 Zechner 1965) result from chronic inflammation. But it is not clear whether in this connection a basal cell on differentiation becomes a secretory and not a ciliated cell (Rhodin, 1959), or whether a ciliated cell undergoes metaplasia into a goblet cell (Spoendlin, 1959). The former mechanism has had more supporters (Latta & Schall, 1934 Lim et al., 1967) In secretory otitis, Lim & Birck (1971) found electron microscopically ciliogenesis in some cells containing secretory granules. This might indicate that the cells were adapting themselves to the transport needs increased by secretory otitis. Since in secretory otitis the epithelium shows a hyperplastic transformation, a proliferation rather than a metaplasia (Lim & Birck, 1971) it does not seem meaningful for a secretory cell population to develop through a highly specialized ciliary cell phase engaged in transport function. It is more probable that the secretory cells differentiate and proliferate directly from the basal cells. The fact that some young ciliating cells show secretory granules is no direct evidence against the above mechanism. Nor can far reaching conclusions be drawn on the basis of the electron microscopic architecture of a few cells. On the other hand, if a certain differentiation of the basal cell begins in a phase of profuse proliferation it may remain partial, and result in the above intermediate forms. The AB- and PAS-positivity of some ciliated cells also may instead of secretory function, indicate an active carbohydrate metabolism of the ciliated cells, e.g. PAS-positivity (without diastase) may show glycogen (as a source of cell energy) The possibility of artifacts and the partial differentiation, mentioned above, also must be taken into consideration in

a cholesteatoma and/or perforation of Shrapnell s membrane in 14 6 per cent of his cases of chronic otitis. Accordingly the present material should have contained three cases of this type. Considering that Scheibe (1917) found a cholesteatoma in 91 and Simpson (1954) in 94 per cent of their cases of chronic otitis with epitympanal perforation it may be assumed that treatment has been sought earlier for ears with cholesteatomatous and, at the same time, often attical processes. In fact, three operated cases were included in the present total material

5.3 2 *Mucosal quality*

The tympanic mucosa in all the cases was thickened to a varying extent Not only mucosal hyperplasia of varying degree but in places also very pronounced oedema and in some cases marked organization fibrosis and even tympanosclerosis (Temporal Bone 9) was seen Granulation processes of different degrees were noted. There were varying numbers of cysts and pseudocysts, and glands were seen in six ears they usually stained positively both with AB and PAS Vascularization varied but was usually abundant.

In 12 temporal bones the tympanal mucosa was infiltrated by inflammatory cells to a varying extent. The predominant types of cells were lymphocytes and plasma cells Polymorphonuclear cells were also seen in a few ears. The subepithelial round cell infiltration formed follicular accumulations in six ears (cf Goerke, 1905 Wittmaack 1926 Singer 1933 T Palva et al., 1964) One patient (Temporal Bones 11 12) had a history of tuberculosis in the lymph nodes of the neck, and another (Temporal Bones 8 10) had been treated in a chest hospital for pulmonary tuberculosis. The follicles however showed nothing suggestive of tuberculosis but apparently represented a mode of reaction typical of the middle ear mucosa in prolonged, chronic inflammation According to Singer (1933) inflammatory cell infiltration acts as the reticuloendothelial system of middle ear mucosa. These cell accumulations may participat in local antibody formation (Zechner 1966)

Squamo-columnar epithelial junctions, in particular were infiltrated by inflammatory cells only once (Temporal Bone 8) In three ears a few lymphocytes were seen under the squamous epithelium up to the junction but from the junction onward their number increased (Temporal Bones 11— 13) and even follicular formations appeared (Temporal Bones 11 12) This finding supported the general impression that the round cell infiltration underneath the squamous epithelium was somewhat less pronounced than under the columnar cuboidal or flat epithelium.

5.3.3 *Epithelium*

5 3.3 1 Columnar cuboidal and flat epithelium

Respiratory epithelium was very common in the middle ear Cilia were seen in all the cases, and they usually continued backward from the unbroken ciliary lining of the orifice of the Eustachian tube and antero-inferior tympanum as one to four tapering tracks. In most temporal bones they remained within the maximal extension limits defined by Sadé (1966 a) but sometimes exceeded them (Hentzer 1970) in the posterior tympanum and epitympanum and even in the region of mastoid air cells (T Palva et al., 1964) Cilia were also occasionally seen on the tympanic surface of the ear drum (e g Temporal Bone 6) In one ear (Temporal Bone 7) the myringitic ear drum was tympanally lined by ciliated columnar epithelium which everted onto its external side. In addition to columnar epithelium cilia appeared at some places on the

cuboidal and even flat epithelium of a few ears.

The ciliated columnar epithelium of an active hyperplastic mucosa was occasionally up to 5—10 cell layers thick. Cuboidal and flat epithelium appeared more often on the fibrotic mucous membranes, free from inflammatory cells e.g. in Temporal Bone 9 the cuboidal and flat, even endothelium like epithelium predominated. These findings support the view that inflammation stimulus produces epithelial hypertrophy (Ojala, 1950) and, especially in chronic infections, hyperplasia and metaplasia (Zechner 1965). According to Friedmann (1959), chronic inflammation causes the reversal of flat epithelium to respiratory type. After inflammation and trophic hyperaemia have disappeared, atrophy again resulting in flat type epithelium takes place (Ojala, 1950).

5.3.3.2. Mucous epithelium and secretory components

The amount of epithelium showing varying degree of mucous change was considerable in about half of the ears. It was most abundant in Temporal Bones 7 and 8 which showed extensive epithelial areas composed almost solely of goblet cells.

In addition to the goblet cells, also columnar and cuboidal secretory cells were seen. Even some ciliated cells showed PAS- and AB-positive material which may suggest a possible secretory function (Sadé, 1966 a). The apical parts of the epithelial cells reacted best to mucus stainings. Glands were noted in six ears, the largest numbers in Temporal Bones 11 and 12. Cysts were visible in all. Both the glandular and the cystic secretion was AB- and PAS-positive. The secretory (mainly goblet) cells were absent from three ears, but even in them, apart from Temporal Bone 9 the epithelium in some places showed PAS-positive and, more faintly AB-positive staining. In Temporal Bone 9 only a few cystic cavities stained PAS- and AB-positively.

It is generally accepted that hyperplastic transformation (Sadé, 1966 b) and increased secretory function of the epithelium (Wittmaack, 1918 Beck, 1926 Singer 1933 Friedmann, 1956 Bendek, 1963 T Palva et al., 1964 Zechner 1965) result from chronic inflammation. But it is not clear whether in this connection a basal cell on differentiation becomes a secretory and not a ciliated cell (Rhodin, 1959) or whether a ciliated cell undergoes metaplasia into a goblet cell (Spoendlin, 1959). The former mechanism has had more supporters (Latta & Schall, 1934 Lim et al., 1967). In secretory otitis, Lim & Birck (1971) found electron microscopically ciliogenesis in some cells containing secretory granules. This might indicate that the cells were adapting themselves to the transport needs increased by secretory otitis. Since in secretory otitis the epithelium shows a hyperplastic transformation, a proliferation rather than a metaplasia (Lim & Birck, 1971) it does not seem meaningful for a secretory cell population to develop through a highly specialized ciliary cell phase engaged in transport function. It is more probable that the secretory cells differentiate and proliferate directly from the basal cells. The fact that some young ciliating cells show secretory granules is no direct evidence against the above mechanism. Nor can far reaching conclusions be drawn on the basis of the electron microscopic architecture of a few cells. On the other hand, if a certain differentiation of the basal cell begins in a phase of profuse proliferation it may remain partial, and result in the above intermediate forms. The AB- and PAS-positivity of some ciliated cells also may instead of secretory function, indicate an active carbohydrate metabolism of the ciliated cells, e.g. PAS-positivity (without diastase) may show glycogen (as a source of cell energy). The possibility of artifacts and the partial differentiation, mentioned above, also must be taken into consideration in

those cases. But it must be said, however that if the cell stains positively both with AB and PAS it is most likely to produce mucous secretion

5.3.3.3 Metaplastic epithelium

Metaplasia in this connection refers to a change of the normal epithelial type, at the site concerned toward some other type There is squamous epithelial metaplasia but also e.g respiratory and glandular metaplasia Changes of respiratory epithelium leading to metaplastic squamous epithelium can be classified as follows (Auerbach et al 1956)

Stage 1 *Basal cell hyperplasia. The stratum* basale undergoes hyperplasia and becomes several layers thick However the overlying (ciliated) columnar epithelium is still present.

Stage 2 Stratification. The superficial cells are flattened and columnar cells have disappeared. Other characteristics of squamous epithelium are not yet visible

Stage 3 Metaplastic squamous epithelium The cells of the superficial layers resemble prickle cells with intercellular bridges

In the present study signs of incipient metaplasia on the tympanic epithelium were interpreted to consist of hyperplasia, increased eosinophilia (in H E) disorganization of cells and nuclei and condensation of cytoplasm These changes correspond mainly to Stage 1 but include also cases originating at a lower epithelium than the respiratory type.

Two kinds of metaplasia could be discerned in the tympanum (1) independent metaplasia of tympanic epithelium and (2) metaplastic epithelium at the junction of tympanic epithelium and the squamous epithelium in continuity with immigrating ear canal epidermis The latter is often a kind of transitional area between squamous and tympanic epithelium.

Metaplasia at least of a slight degree in one or both of the above forms was seen in all ears of the present material although in two ears the finding was slight and uncertain (Temporal Bones 6 9). Distinct independent metaplasia was seen in six ears (and uncertain findings in Temporal Bones 6, 7 9). Junction metaplasia was seen in 11 ears.

5.3.3.3 1 Independent metaplasia

In three ears the change remained at the stage of basal hyperplasia, in one ear at the stage of stratification and in two ears (both involving a moist total perforation of the pars tensa) prickles were seen as indication of true metaplastic squamous epithelium *No keratin or granular cell layer* was seen In these two cases (Temporal Bones 10 11) there was pseudoparakeratotic sealing of the metaplastic squamous epithelium which covered a relatively fibrotic *promontorial connective tissue. In two* uncertain cases (Temporal Bones 6, 9) the degree of metaplasia was so low that not even a true basal hyperplasia could be noted The only changes seen were a *slightly increased number of cell layers, and* disorganization of epithelial cells. In one case (Temporal Bone 7) basal hyperplasia was localized along the margins of the perforation on the ear canal side, beneath the everted columnar epithelium, the thickness of the basal cell layer varying from 2—3 to over 10 cells. In six of these nine ears metaplasia was seen on the promontorial mucosa All cases of stratification or true squamosity *(Auerbach s 2nd and 3rd stages)* belonged to this group

5 3 3.3.2 Junction metaplasia

Junction metaplasia was noted in 11 ears In six of them independent *metaplasia was* also recorded In one ear the squamo-columnar junction was so abrupt throughout, that no metaplastic zone of transition could be seen The epidermis with all its layers, *ended abruptly and sometimes* the very next cell was a flat endothelium-like cell (Tem

poral Bone 9 Fig. 77) Furthermore, in one ear (Temporal Bone 6) the squamous epithelium at the perforation edge grew into the ear drum stroma but not onto the tympanic surface, and therefore there could be no junction metaplasia (Figs. 49 50). In all the other ears with immigration there was a transitional area of varying width, although sometimes in the same ear clear cut junctions at different levels and different sites of the perforation could be seen in addition to junction metaplasia. The width of junction metaplasia ranged from 0.1 to 2.0 mm, average 0.5 mm.

Junction metaplasia cannot be described by the various degrees of metaplasia, as can independent metaplasia. The epithelial change was often gradual and the evident squamous-type epithelium still belonged to the immigration process. Junction metaplasia, on the other hand, referred to the less thick and often relatively simple "junctional" epithelium which could not yet be classified as post-immigration tympanic nor any longer as squamous epithelium. A longer stretch of pseudoparakeratotically scaling junction metaplasia with prickle cells was seen in one ear (Temporal Bone 12), and a mainly stratification-type change in two ears (Temporal Bones 8, 10).

Inflammation of the ear canal contiguous to the ear drum, and epithelial immigration were seen in seven of the 11 ears with junction metaplasia. In three ears (Temporal Bones 11—13) with junction metaplasia and pronounced immigration, the ear canal skin near the drum had already healed and become fibrotic. The fourth ear with immigration but free from ear canal inflammation was the only dry ear (Temporal Bone 9).

5.3.3.4 Immigrating squamous epithelium

The middle ear epidermis and squamous epithelium which are in continuity with the ear canal epidermis are here called immigrating. Any tympanic epidermis found in the material was always continuous, with the epidermis of the ear canal or ear drum covering varying distances from perforation edges towards the tympanum. There was no case in the material of epidermis occurring solitarily in the tympanum, except one implantation islet in Temporal Bone 11 without continuity to the ear canal and/or ear drum epidermis. The conclusion to be drawn is that any epidermis seen tympanally is a result of epidermal ingrowth.

Immigrating squamous epithelium was seen in all cases, except Temporal Bone 7 with the epithelial eversion (emigration). Depth growth of squamous epithelium, primarily on junction areas, was seen in five ears, and in one of them (Temporal Bone 6) the immigration only took the form of a subepithelial squamous projection into the tympanic side of ear drum stroma. Also in Temporal Bone 7 the squamous epithelium was seen to send projections underneath the everted epithelium into the subepithelial granulation tissue of the ear drum, although these did not extend onto the middle ear side.

Regardless of the type of perforation, the ear canal/ear drum epidermis showed growth activity on the junctional area. In the ears where the immigration was most pronounced the epidermis was often slightly thickened near the junction, whereas the basement membrane, with the present methods of study failed to show any specific correlations in this area. Nor was the ear canal inflammation directly correlated with the immigration, although findings suggested subsidence of ear canal inflammation in cases where immigration was most pronounced. On the other hand, mainly subepithelial inflammatory cell infiltration in the middle ear was present in all cases, except for Temporal Bone 9 in which case the ear was dry. The infiltration, however did not seem to be specifically localized in the junction areas.

The width of the transitional area of immigrating squamous epithelium varied from an abrupt change (four ears) to various degrees of a stepwise transition A gradual disappearance of epidermal characteristics could often be noted Frequently *there was a parakeratotic intermediary stage* suggestive of a more primitive keratinization type often followed by the pseudoparakeratotic stage *free from keratinization* before the epithelium was transformed into the normal tympanic types

Sliding an intrusion of the squamous epithelium for a distance of 0 1 to 0 2 mm between the columnar epithelium and the basement membrane, or above the columnar epithelium was seen in three ears All cases with sliding were among the ears with abrupt transition i e. the immigrating squamous epithelium pushed aside the tympanic epithelium and intruded itself underneath (or above) it The situation was not distinctly correlated with the other pathoanatomical subepithelial changes

The most remarkable histopathological finding in connection with immigration was the correlation between its extent and the kind of perforation Although immigration *was seen in almost all ears with central* perforation its extent towards the tympanum was only of an average order of 0.5—0 6 mm The more extensive immigration extending to the promontory (three cases) always occurred among the ears with a total perforation of pars tensa In partly marginal perforations of the pars tensa, the width of immigration was between the above two groups In all three ears with promontorial immigration there was a formation of connective tissue bridges to the medial tympanic wall but in these cases there was also *extensive immigration elsewhere* than along the bridges

Although no instance of attic perforation was seen the ear canal epidermis at the annular area of Shrapnell s membrane showed acanthosis in five ears and even a tendency to depth growth in two. These cases correlate well with the five ears described earlier (p 93) in which depth growth was seen at the junction of the immigrating squamous epithelium (four of them belonged to both groups) Furthermore, the two ears with the depth growth at the region of Shrapnell s membrane also coincided with the ears with pronounced immigration (Temporal Bones *11 12) The inflammation of the ear canal,* on the other hand was in no way correlated with these seven ears (cf Eigler 1951)

5.3 4 *Other findings*

5 3 4 1 Eversion of tympanal epithelium

In two ears the tympanic epithelium was seen to evert (emigrate) onto the ear canal side of the perforation edges This phenomenon was particularly marked in Temporal Bone *7* in which ciliated pseudostratified columnar epithelium with goblet cells could be seen extensively on the ear canal side of the drum In places this everted epithelium was also *mucously changed or metaplastic* The eversion in both cases of the present series, was caused of chronic myringitis in *the edges of central perforation*

5.3 4.2 Epidermal implantation

Epidermal implantation was seen in Temporal Bone 11 This solitary islet of squamous epithelium consisting of stratum basale stratum spinosum and even some granular cells, surrounded by tympanic columnar epithelium and 0.2 mm in diameter had superficial cells showing a slight tendency to parakeratotic scaling *Almost the only way it* could have developed was that a group of cells of the immigrating epidermis had been *implanted there without* epidermal continuity out of the pouch

5 3 4 3 Cholesterol cyst

A cyst containing cholesterol crystals was found in Temporal Bone 12 Such a cyst is

seen in difficult drainage conditions in chronic otitis and can develop into a cholesterol granuloma (Friedmann, 1959).

5.3.4.4 Tympanosclerosis

Tympanosclerosis implies hyalinization and later scleroting of the collagenous scar tissue in the tympanum and tympanic membrane. It was seen on the ear drum of the only completely dry ear of the material (Temporal Bone 9). Also Temporal Bone 4 showed characteristics slightly suggestive of tympanosclerosis in the posterior parts of the ear drum remnants.

5.4 TYMPANAL SQUAMOUS EPITHELIUM

Stratified squamous epithelium was seen on the tympanal mucosa in 11 ears, and exceptions were made by the two with eversion. The 11 middle ears showed immigrating squamous epithelium and in five or six of them it was located only in the neighbourhood of the perforation. Metaplastic squamous epithelium was present in only three ears, and in two it contained prickles on the promontory surface. In no instance did the metaplastic epithelium show stratum granulosum or keratinization.

Squamous epithelium occurred on the promontory in six ears, equally divided between metaplastic and immigrating types. This change coincided with the total pars tensa defects: independent metaplasia and immigration were only once, respectively, associated with central perforation of the pars tensa. In all six ears the perforation was moist (two ears) or purulent (four ears).

On the tympanic side, only the immigrating type showed epithelium with all the characteristics of epidermis (epidermization). In two ears (Temporal Bones 12, 13) of distinct promontorial immigration the squamous epithelium retained its keratinizing epidermal characteristics almost throughout, the promontory included. Once (Temporal Bone 12) it was even "aggressively" hyperkeratotic. In four ears (Temporal Bones 9, 11—13) of the most extensive immigration (and one of eversion, Temporal Bone 7), the epidermis thickened at or immediately before the junction for a distance of a few tenths of a millimetre. In two ears (Temporal Bones 11, 13), increased subepithelial inflammatory cell infiltration was seen from the junction onwards.

The etiology of both promontorial and true tympanic, squamous epithelium seemed to be metaplastic just as often as it was immigrating. The tendency to keratosis and depth growth, on the other hand, seemed to belong to the immigrating type only. The presence of connective tissue bridges also indicated immigration, although in these cases an extensive immigration from elsewhere was also noted at the same time. The type of the perforation of pars tensa was important in that both the immigration and the metaplasia were more extensive where the perforation had been total.

5.5 KERATINIZATION, CHOLESTEATOMA (EPIDERMOSIS)

Opinions concerning a metaplastic etiology of keratinizing squamous epithelium in the middle ear are contradictory. Friedmann (1959) and Lim & Saunders (19 2) are among those who found no signs of keratinization in metaplastic squamous epithelium, whereas Sadé (1971) was of the opinion that a metaplastic etiology of cholesteatoma is possible. As early as 1890, Haycroft & Carlier had claimed that the tracheal ciliated epithelium could, under the influence of friction, undergo metaplasia into squamous epithelium and even become keratinized. Auerbach (1956) reported that bronchial ciliated epithelium responded to irritation by squamous epithelial metaplasia showing also prickle cells, but the epithelium was not

The width of the transitional area of *immigrating squamous epithelium* varied from an abrupt change (four ears) to various degrees of a stepwise transition A gradual disappearance of epidermal characteristics could often be noted Frequently there was a parakeratotic intermediary stage suggestive of a more primitive keratinization type, often followed by the pseudoparakeratotic stage free from keratinization before the epithelium was transformed into the normal" tympanic types.

Sliding an intrusion of the squamous epithelium for a distance of 0 1 to 0.2 mm between the columnar epithelium and the basement membrane or above the columnar epithelium was seen in three ears All cases with sliding were among the ears with abrupt transition i e the immigrating squamous epithelium pushed aside the tympanic epithelium and intruded itself underneath (or above) it. The situation was not distinctly correlated with the other pathoanatomical subepithelial changes.

The most remarkable histopathological finding in connection with immigration was the correlation between its extent and the kind of perforation Although immigration was seen in almost all ears with central perforation its extent towards the tympanum was only of an average order of 0.5—0 6 mm The more extensive immigration extending to the promontory (three cases) always occurred among the ears with a total perforation of pars tensa. In partly marginal perforations of the pars tensa, the width of immigration was between the above two groups. In all three ears with promontorial immigration there was a formation of connective tissue bridges to the medial tympanic wall but in these cases there was also extensive immigration elsewhere than along the bridges.

Although no instance of attic perforation was seen the ear canal epidermis at the annular area of Shrapnell s membrane showed acanthosis in five ears and even a tendency to depth growth in two These cases correlate well with the five ears described earlier (p 93) in which depth growth was seen at the junction of the immigrating squamous epithelium (four of them belonged to both groups) Furthermore the two ears with the depth growth at the region of Shrapnell s membrane also coincided with the ears with pronounced immigration (Temporal Bones 11 12) The inflammation of the ear canal on the other hand was in no way correlated with these seven ears (cf Eigler 1951)

5.3 4 *Other findings*

5 3 4 1 Eversion of tympanal epithelium

In two ears the tympanic epithelium was seen to evert (emigrate) onto the ear canal side of the perforation edges This phenomenon was particularly marked in Temporal Bone *7* in which ciliated pseudostratified columnar epithelium with goblet cells could be seen extensively on the ear canal side of the drum. In places this everted epithelium was also mucously changed or metaplastic. The eversion in both cases of the present series, was caused of chronic myringitis in the edges of central perforation

5.3 4.2 Epidermal implantation

Epidermal implantation was seen in Temporal Bone 11 This solitary islet of squamous epithelium, consisting of stratum basale, stratum spinosum and even some granular cells, surrounded by tympanic columnar epithelium and 0.2 mm in diameter had superficial cells showing a slight tendency to parakeratotic scaling *Almost the only way it* could have developed was that a group of cells of the immigrating epidermis had been implanted there without epidermal continuity out of the pouch

5.3 4 3 Cholesterol cyst

A cyst containing cholesterol crystals was found in Temporal Bone 12. Such a cyst is

sites in difficult drainage conditions in chronic otitis and can develop into a cholesterol granuloma (Friedmann, 1959).

5.3.4.4 Tympanosclerosis

Tympanosclerosis implies hyalinization and later sclerosing of the collagenous scar tissue in the tympanum and tympanic membrane. It was seen on the ear drum of the only completely dry ear of the material (Temporal Bone 9). Also Temporal Bone 4 showed characteristics slightly suggestive of tympanosclerosis in the posterior parts of the ear drum remnants.

5.4 TYMPANAL SQUAMOUS EPITHELIUM

Stratified squamous epithelium was seen on the tympanal mucosa in 11 ears, and exceptions were made by the two with eversion. The 11 middle ears showed immigrating squamous epithelium and in five or six of them it was located only in the neighbourhood of the perforation. Metaplastic squamous epithelium was present in only three ears, and in two it contained prickles on the promontory surface. In no instance did the metaplastic epithelium show stratum granulosum or keratinization.

Squamous epithelium occurred on the promontory in six ears, equally divided between metaplastic and immigrating types. This change coincided with the total pars tensa defects independent metaplasia and immigration were only once, respectively associated with central perforation of the pars tensa. In all six ears the perforation was moist (two ears) or purulent (four ears).

On the tympanic side, only the immigrating type showed epithelium with all the characteristics of epidermis (epidermization). In two ears (Temporal Bones 12, 13) of distinct promontorial immigration the squamous epithelium retained its keratinizing epidermal characteristics almost throughout, the promontory included. Once (Temporal Bone 12) it was even "aggressively" hyperkeratotic. In four ears (Temporal Bones 9 11—13) of the most extensive immigration (and one of eversion, Temporal Bone 7) the epidermis thickened at or immediately before the junction for a distance of a few tenths of a millimetre. In two ears (Temporal Bones 11 13), increased subepithelial inflammatory cell infiltration was seen from the junction onwards.

The etiology of both promontorial and true tympanic, squamous epithelium seemed to be metaplastic just as often as it was immigrating. The tendency to keratosis and depth growth, on the other hand, seemed to belong to the immigrating type only. The presence of connective tissue bridges also indicated immigration, although in these cases an extensive immigration from elsewhere was also noted at the same time. The type of the perforation of pars tensa was important in that both the immigration and the metaplasia were more extensive where the perforation had been total.

5.5 KERATINIZATION CHOLESTEATOMA (EPIDERMOSIS)

Opinions concerning a metaplastic etiology of keratinizing squamous epithelium in the middle ear are contradictory. Friedmann (1959) and Lim & Saunders (1972) are among those who found no signs of keratinization in metaplastic squamous epithelium, whereas Sadé (1971) was of the opinion that a metaplastic etiology of cholesteatoma is possible. As early as 1890 Haycroft & Carlier had claimed that the tracheal ciliated epithelium could, under the influence of friction, undergo metaplasia into squamous epithelium and even become keratinized. Auerbach (1956) reported that bronchial ciliated epithelium responded to irritation by squamous epithelial metaplasia showing also prickle cells, but the epithelium was not

The width of the transitional area of immigrating squamous epithelium varied from an abrupt change (four ears) to various degrees of a stepwise transition A gradual disappearance of epidermal characteristics could often be noted Frequently there was a parakeratotic intermediary stage suggestive of a more primitive keratinization type, often followed by the pseudo-parakeratotic stage free from keratinization before the epithelium was transformed into the normal tympanic types.

Sliding an intrusion of the squamous epithelium for a distance of 0 1 to 0.2 mm between the columnar epithelium and the basement membrane, or above the columnar epithelium was seen in three ears. All cases with sliding were among the ears with abrupt transition i e. the immigrating squamous epithelium pushed aside the tympanic epithelium and intruded itself underneath (or above) it. The situation was not distinctly correlated with the other pathoanatomical subepithelial changes.

The most remarkable histopathological finding in connection with immigration was the correlation between its extent and the kind of perforation Although immigration was seen in almost all ears with central perforation its extent towards the tympanum was only of an average order of 0.5—0 6 mm. The more extensive immigration extending to the promontory (three cases) always occurred among the ears with a total perforation of pars tensa. In partly marginal perforations of the pars tensa, the width of immigration was between the above two groups In all three ears with promontorial immigration there was a formation of connective tissue bridges to the medial tympanic wall but in these cases there was also extensive immigration elsewhere than along the bridges

Although no instance of attic perforation was seen the ear canal epidermis at the annular area of Shrapnell's membrane showed acanthosis in five ears and even a tendency to depth growth in two These cases correlate well with the five ears described earlier (p 93) in which depth growth was seen at the junction of the immigrating squamous epithelium (four of them belonged to both groups) Furthermore, the two ears with the depth growth at the region of Shrapnell's membrane also coincided with the ears with pronounced immigration (Temporal Bones 11 12) The inflammation of the ear canal on the other hand, was in no way correlated with these seven ears (cf Eigler 1951)

5 3 4 *Other findings*

5.3 4 1 Eversion of tympanal epithelium

In two ears the tympanic epithelium was seen to evert (emigrate) onto the ear canal side of the perforation edges. This phenomenon was particularly marked in Temporal Bone 7 in which ciliated pseudostratified columnar epithelium with goblet cells could be seen extensively on the ear canal side of the drum In places this everted epithelium was also mucously changed or metaplastic. The eversion in both cases of the present series, was caused of chronic myringitis in the edges of central perforation

5 3 4.2 Epidermal implantation

Epidermal implantation was seen in Temporal Bone 11 This solitary islet of squamous epithelium consisting of stratum basale stratum spinosum and even some granular cells, surrounded by tympanic columnar epithelium and 0.2 mm in diameter had superficial cells showing a slight tendency to parakeratotic scaling Almost the only way it could have developed was that a group of cells of the immigrating epidermis had been implanted there without epidermal continuity out of the pouch

5.3 4 3 Cholesterol cyst

A cyst containing cholesterol crystals was found in Temporal Bone 12 Such a cyst is

the middle ear surfaces and is slightly or normally keratinizing, or one that is hyper keratotic, "aggressive" and cholesteatoma forming. Only in Temporal Bone 12 did the epidermis show changes suggestive of the latter type, even then with no cholesteatoma as yet. Had the epidermis in this case (with a medical history exceeding 60 years) originally been cholesteatoma forming, it would definitely already have complicated the otitis with a strong cholesteatomatous process. It is therefore probable that some mesenchymal induction mechanism in a later phase has stimulated the epidermis to change into an active type, hyperkeratotic in character. The patho-anatomical drainage conditions in this case did not differ from those of the rest of the material, a factor to corroborate the view that there must be some mesenchymal inductor(s) present in the transformation of epidermis into the cholesteatomatous type. The high rate of the coincidence of a perforation of Shrapnell's membrane and cholesteatoma, on the other hand, seems to indicate the importance of the patho-anatomical, i.e. drainage conditions. However the marked growing tendency of the epidermis at the region of pars flaccida might also indicate that certain mesenchymal induction mechanisms were particularly epitympanally localized and that even here, in addition to the difficult drainage conditions, also epithelio-subepithelial interactions may contribute for the formation of cholesteatoma.

A comparison of enzymology in cholesteatomatous and non-cholesteatomatous epidermis showed that enzyme activity was usually more pronounced in the cholesteatomatous type (T Palva et al., 1970 a). According to these authors, the most important qualitative differences were observed in acid phosphatase, 5-nucleotidase and non-specific esterases (see also T Palva et al., 1971). Recent quantitative analyses (T Palva et al., in press) of alkaline and acid phosphatase activities of cholesteatoma epithelium and postauricular skin showed significantly larger values in the former tissue.

Abramson & Gross (1971) in cases of cholesteatoma, found that the frequency of collagenase activity in tissue culture containing both the epithelium and the mesenchyma was nearly thrice its frequency in cultures containing only the one or the other. Consequently epithelo-mesenchymal interactions increase collagenase activity and hence also further the development of the destructive process of cholesteatoma.

Collagenase activity in non-cholesteatomatous as opposed to cholesteatomatous epithelial mesenchyma in the middle ear has not been studied. Research of this type, and other tissue culture studies concerned with the interrelationships of middle ear mucosa, middle ear epithelium and mesenchyma will, in the future, evidently shed more light on the problems of the behaviour of middle ear epithelium, the mechanisms of induction, and epidermosis.

keratinized Salm (1957) described epidermoid metaplasia in mammary fibroadenoma with formation of keratin cysts. Furthermore, it is known that e.g in leucoplakia of the oral mucous membranes, both keratinization and a granular cell layer are seen on the squamous epithelium which usually is free from the stratum granulosum (Andrews & Domonkos, 1963)

According to McLoughlin (1961 b) each type of mesenchyma has a characteristic influence on the overflying epithelium. The epidermis of the limb-bud of a five-day old chick embryo was keratinized in isolation (McLoughlin 1961 a) and on dermal mesenchyma (McLoughlin 1961 b) On the gizzard mesenchyma, it became mucus secreting and even ciliated On the central myoblastic area of heart mesenchyma the epidermis became endocardial and on the peripheral fibroblastic area it keratinized extensively Moscona (1961) found that, in 19-day old chick embryos, the epidermis on the mesenchyma of the oviduct keratinized when this explant was treated with oestradiole benzoate, the epidermis was transformed into a typical columnar mucus-secreting epithelium When isolated epidermis was treated with oestrogen, no mucous transformation took place, a sign that mesenchyma was required to mediate this effect According to McLoughlin (1961 b) epithelial differentiation is effected by means of the different intercellular materials produced by fibroblasts and more specifically by means of the basement membrane Mesenchymal induction must also be continuous in order to create and maintain the desired differentiation of the epidermis Fell (1964) on the basis of the work by Wessells (1962) and Dodson (1963) assumed that a condition for keratinization and differentiation of the epidermis is the influence of a substrate permitting the specific polarization of the basal cells

According to Lasnitzki (1963) vitamin A deficiency enhanced keratinization and an addition of vitamin A to a culture (embryonic rat oesophagus) changed the epithelial cells into a mucous type with goblet cells Fitton Jackson & Fell (1963) found also mucous metaplasia in skin cultures (scaly metatarsal skin from 12-day chick embryos) treated with vitamin A After the termination of the effect of vitamin A the keratinization qualities were regenerated, and some basal cells, as they moved up into the central epidermal layers, showed both secretory globules and pre-keratinous filaments, i.e. mucin and keratin synthesis in the same cell According to Moscona (1961) the secretory epithelium may also be keratinized as the oxygen pressure increases, and raising the CO_2 pressure to the normal level inhibits this keratogenic metaplasia in chorionic ectoderm of incubated egg

Although a great deal of theoretical and experimental evidence in favour of keratinizing squamous epithelial metaplasia has been accumulated, the present results corroborate the view that metaplastic squamous epithelium in the middle ear hardly ever keratinizes. In the two middle ears in which metaplasia into the stage of stratified squamous epithelium (with prickle cells) was seen the medical history covered a minimum of 40 years and there was no stratum granulosum or keratinization Thus the cholesteatomatous etiology cannot, in the present author's opinion be explained on the metaplastic basis.

The depth growth of immigrating squamous epithelium at the junctions and the hyperactivity of the epidermis at the annular region of the pars flaccida are very well correlated The cases with the latter phenomenon those of the most pronounced immigration, those with the thickening of squamous epithelium at the junction and the "aggressive" hyperkeratosis in one ear are also correlated. In suitable conditions, all this may lead to the development of epidermosis.

It is apparent that tympanic epidermis may be of two types either one that covers

is adequate, together with a subtotal excision of the promontorial mucosa. It is possible that remnants of squamous epithelium can then even be converted to ordinary "tympanal" epithelium. But when tympanoplasty cuts off the immigration bridges it is also possible that the natural horizontal migration of even minute keratin amounts is inhibited, with the result that an epidermosis develops. In case of cholesteatoma, owing to the high risk of recurrence, the "aggressively" behaving, expansive epidermo-mesenchymal system always requires a total removal. If at the operation no distinct line can be drawn between the immigrating squamous epithelium and the above system, it is advisable always to remove all the epithelium that is suspected of being squamous.

6 CONCLUSIONS

The middle ear epithelium reacts to chronic inflammation by hypertrophy hyperplasia, metaplasia, squamous metaplasia, and secretory proliferation Not only immigration of squamous epithelium but also epidermization and even epidermosis may occur Emigration of tympanic epithelium is also possible in certain conditions From the present study of the epithelium of chronically infected middle ear the following conclusions, based on 13 serially sectioned temporal bones, can be drawn

1 Respiratory type epithelium which often was secretory lined the middle ear cavity remarkably widely exceeding the limits of the maximal extension reported by Sadé (1966 a) It was localized for the most part in the anterior and inferior tympanum with the cilia extending backward in the form a few (one to four) tapering strips.
2 Epithelial metaplasia, of a mild degree at least, occurred regularly in the chronically infected middle ear
3 Stratified squamous epithelium was present on the tympanic mucosa in most cases The promontorial stratified squamous epithelium was as often of metaplastic as of immigrating origin
4 Metaplastic squamous epithelium showed no tendency to keratinization in any of the cases
5 Immigrating squamous epithelium largely retained its epidermal characteristics and slight keratinizing properties In only one case was it transformed into aggressive looking hyperkeratotic epithelium with a prominent stratum granulosum
6 It is apparent that there must be some mesenchymal induction system which in connection with certain patho-anatomical environmental factors (drainage difficulties, pressure effects on the epithelium attic perforation moisture etc.), makes the squamous epithelium aggressive" hyperkeratotic, cholesteatoma forming The present results corroborate the findings by T Palva et al (1968) and Sadé (1971) that there are various types of squamous epithelium in the middle ear
7 When an operation is performed for chronic otitis media, even if nothing suggestive of cholesteatoma can be seen intraoperatively either by the naked eye or with an operating microscope, there is almost always some amount of squamous epithelium on the tympanic side of the perforation edges or in the tympanum. (Cholesteatoma cholesteatomatous membrane and immigrated epidermis can usually be seen under the operating microscope, though observation of the latter can be somewhat difficult) This finding places added importance to the swing-door plasty recommended by T Palva et al (1969) for both myringo- and tympanoplasties, since it permits a careful inspection of the tympanic side of the drum (edges) and its de-epithelialization and possible de-epidermization

The tympanal squamous epithelium seen is either metaplastic or immigrating It is not necessary to remove the metaplastic, nonkeratinizing squamous epithelium at the operation An immigrating non hyperkeratotic squamous epithelium without an extra induction system, will apparently not change its type In these cases removal of epithelium from the epi and hypotympanum to the perforation edge

that there exist two types of squamous epithelium in the chronically infected middle ear The serial section method, however suggests that the non-cholesteatomatous type of squamous epithelium is either immigrating or metaplastic in origin, whereas the cholesteatomatous type is always immigrating The metaplastic type does not undergo keratinization, and the non-cholesteatomatous immigrating type may retain its properties of slight keratinization permanently and never change into cholesteatomatous, "aggressive" and expansive system of epidermal mesenchyma unless inductors unknown to date are present.

Since the ear drum epidermis regularly grows to the tympanal side of the perforation edges, the swing-door plasty recommended by T Palva et al. (1969) is advisable in all operations on the chronically infected ear This technique permits exact operative removal of the tympanic epidermis In an ordinary non-hyperkeratotic case, a subtotal excision of the mucosa in addition to the marginal de-epithelialization is sufficient. In a case with metaplastic squamous epithelium in the tympanum, it is not necessary to touch the epithelium at all unless this is required because of other tympanic pathology A cholesteatomatous process can always be seen with the operating microscope (keratotic, light coloured cholesteatomatous membrane) and when this happens, a total removal of the transformed middle ear epithelium is indispensable owing to the risk of recurrence.

In practice, a complete removal of the squamous epithelium if intraoperatively observed in the tympanum is usually the wisest course in operations with closed techniques.

7 SUMMARY

The purpose of the present study was to examine systematically the epithelium of the chronically inflamed middle ear. Particular attention was given to the type, origin and keratinization characteristics of the squamous epithelium possibly found in the tympanum and to the relationship between the epithelial changes observed and the tympanal pathology in general.

Autopsy material comprised 13 chronically infected middle ears, often with a medical history of decades. The temporal bones were serially sectioned after fixation and decalcification. The sections were stained with seven methods: Haematoxylin-Eosin, Alcian Blue, PAS, Baker, Luxol Fast Blue, and modifications by Ladewig and Ayoub-Shklar of the Mallory stain. The main method was the H-E on which systematical analysis was based.

The middle ear epithelium was found to react to chronic inflammation by hypertrophy, hyperplasia, secretory proliferation, metaplasia and squamous metaplasia. Immigration of squamous epithelium, epidermization and even epidermosis were also encountered. Emigration of the tympanic epithelium was also possible in certain cases.

As a rule, respiratory epithelium, which often was secretory, lined the tympanic cavity widely in its anterior and inferior parts, extending in some ears to the inner surface of the tympanic membrane, to the epitympanum, posterior tympanum and even to the area of the mastoid air cell system. The tubo-tympanic ciliated epithelium continued posteriorly in the form of a few (one to four) tapering strips, which were mainly localized inferiorly and extended in some ears up to the posterior limits of the middle ear cleft.

Epithelial metaplasia of varying degree was seen in all ears. In no case did the metaplastic squamous epithelium, even if stratified, show any signs of keratinization.

A certain extent of immigrating squamous epithelium with all its layers except rete pegs was seen in most ears at least in the area of the perforation edge. The junction between the epidermis and the tympanal epithelium varied from a completely abrupt change to a gradual change with a transitional area of varying width. Immigration was slightest in cases with central perforation. In total perforations of pars tensa the squamous epithelium immigrated extensively into the tympanum, reaching over the perforation edges and along connective tissue bridges even to the promontory. The promontorial stratified squamous epithelium seen in six cases was as often of metaplastic as of immigrating origin.

Immigrating squamous epithelium retained largely the normal characteristics typical of the drum epidermis. In one case only was it transformed into an "aggressive" looking hyperkeratotic epidermotic epithelium with a prominent stratum granulosum and showing in some places subepithelial projections.

On the basis of the above findings and bearing in mind that the material contained no distinct cholesteatoma, it seemed that not until there is some mesenchymal induction system, in connection with certain patho-anatomical conditions (attic perforation, pressure effects on the epithelium, particular inflammatory conditions, etc.) does the squamous epithelium become cholesteatomatous.

The present findings support the observations reported by T. Palva et al. (1968)

8 ACKNOWLEDGEMENTS

Chronic otitis media has for years been one of the main research projects, both clinical and histochemical in the Oulu University Department of Otolaryngology. Professor Tauno Palva, M.D., Head of the Department, my teacher and chief suggested the present subject of the study programme to me, and arranged all the facilities for this investigation. With his expert advice, he skilfully guided me from the very beginning of my work to the completion of the manuscript. I owe him my deepest gratitude.

I am also deeply indebted to my other supervisor Professor Kai Dammert, M.D. Head of the Department of Pathology Oulu University. He placed his laboratory at my disposal advised me in the analyzing of the histological specimens and gave me valuable and constructive criticism during the preparation of the manuscript.

My sincere thanks are due to Professor Leo Ojala, M.D., Head of the Department of Otolaryngogology Central Hospital, Tampere. His expertise in this study field made his advice very valuable to me while I was writing this thesis.

I wish to thank Mr Heikki Nieminen and Mrs Seija Nieminen for preparing the numerous microphotographs. Also my best thanks are due to Mrs Hilkka Kontiopää, M.A., for translating the Finnish manuscript and Mrs Barbara Rikberg for checking the English language as well as to Mrs Leena Manninen, commercial correspondent, for typing the manuscript, to Mrs Irja Jouhten and Mrs Maija Korvala for preparing the histological specimens, and to Mrs Pirkko Orell for help in the collection of literature.

My study was assisted by grants from the Oulu Research Council for Medical Sciences and Korvatautien Tutkimussäätiö.

Oulu, November 1977

En aucune autre partie de l'organisme, on ne trouve rassemblées, en un si petit espace, des formes anatomo-pathologiques si diverses, depuis le simple envahissement des muqueuses et des tissus connectivo-vasculaires lâches sous-muqueux, sous l'aspect exophytique, jusqu'à l'infiltration des divers groupes musculaires laryngiens et jusqu'à la destruction cartilagineuse ou osseuse soit du thyroïd, soit du cricoïde, soit de l'arytenoïd, soit de l'épiglotte, soit même de l'os hyoïde. »

(Coutard, 1937)

"In no other part of the body does one find gathered together in so small space, anatomo-pathological forms so diverse, from the simple invasion of the mucosa and loose vasculo-connective tissues and submucosae, of an exophytic aspect, to the infiltration of the various laryngeal muscular groups, and to the cartilaginous or osseous destruction of the thyroid, or the cricoid, or the arytenoid, or the epiglottic or even of the hyoid."

(Coutard, 1937 translated by Cantrill, 1959)

Dr Olofsson is now in the D-partment of Otolaryngology
Linköping University Linkoping, Sweden

TABLE OF CONTENTS

INCIDENCE

It is estimated that in the United States of America in the year 1972, 650 000 new cases of cancer will be diagnosed (Silverberg & Holleb 1972). The death rate from cancer at all sites is estimated as 345 000. In the same period of time, it is expected that 6 800 new cases of laryngeal carcinoma will be diagnosed, and that 3 050 will die of this disease. Whereas the ratio of male to female is nearly equal in the cancers from all sites, laryngeal cancer is expected to be diagnosed in 6 000 male patients, but in only 800 female patients (males/females = 7.5 : 1). The National Board of Health and Welfare, The Cancer Registry in Sweden (1971) reported 155 564 new carcinomas during the period 1959–1965. The mean population in Sweden during this time was 7.6 million people. 826 new laryngeal carcinomas were reported during this period. The crude annual incidence of laryngeal carcinoma per 100 000 individuals is 2.8 for the males and 0.3 for the females. Laryngeal carcinoma constitutes 1 % of all cancer among males and 0.1 % among females. The sex ratio (crude) in this Swedish series is 9.3 : 1 (male : female). There is an urban predominance in males which is lacking in females. The incidence of carcinoma of the larynx appears to parallel the rising incidence of bronchial carcinoma (Ackerman & del Regato, 1970). On the other hand, the incidence of hypopharyngeal carcinoma appears to follow more closely the incidence of carcinoma of the oral cavity (Ackerman & del Regato 1970), and does not appear to be rising in the same degree. A male predominance is also seen in the hypopharyngeal tumours with the exception of postcricoid carcinomas which have the reverse sex incidence (Jacobsson, 1951; Ackerman & del Regato 1970; Jørgensen, 1971). 446 new cases of hypopharyngeal carcinoma were reported in Sweden during the period 1959 through 1965 with the ratio of male to female = 1.3 : 1 (crude) (National Board of Health & Welfare, The Cancer Registry 1971).

The vast majority of malignant tumours arising in the larynx and hypopharynx are squamous cell carcinomas, all other types of malignancy arising in this region are rare.

The overall ratio of laryngeal to hypopharyngeal carcinoma varies from country to country (Ackerman & del Regato 1970). (In Toronto approximately 100 new cases of laryngeal carcinoma are seen in a year compared to approximately 30 new cases of hypopharyngeal carcinoma (Bryce, 1972).)

Within the larynx, the major published series report that tumours arising in the glottic region are much more frequent than tumours arising in the supraglottic region (MacComb & Fletcher 1967; Mårtensson et al. 1967; Ackerman & del Regato, 1970; American Joint Committee (AJC), 1971; Ledermann 1971). However in Finland, Lauerma (1967) and Taskinen (1969) report that 67 % of all laryngeal carcinomas arise in the supraglottic region, in Spain Pastor (1969) in a review of 1 056 laryngeal carcinomas reports 60 % and in Italy Pietrantoni & Fior (1958) report that over 50 % arise in the same region. In most series primary subglottic tumours are relatively infrequent (Pietrantoni & Fior 1958; Taskinen, 1969)—usually less than 5 % (Smith et al., 1961; MacComb & Fletcher 1967; Mårtensson et al. 1967; AJC, 1971). Lederman (1971) reported a figure close to 8 %. Within the hypopharynx, in most series at least 50 to

ryngeal and hypopharyngeal carcinomas in relation to the site of origin of the tumour

Many previous authors (e g Mc'Kenty 1926 St. Clair Thomson & Colledge, 1930 Broyles, 1943 Baclesse, 1949 Ogura, 1955 Tucker 1961 1963 Kirchner 1969 Norris et al 1970) have pointed out different sites of weakness in the laryngeal framework through which the tumours tend to spread. Did our material support their findings?

We studied the specific anatomy in the anterior commissure region and applied this anatomical knowledge in a clinical survey of anterior commissure carcinoma to explain the early invasion of cartilage and spread outside the larynx through the cricothyroid membrane so typical of these tumours

A clinical study to evaluate the effect of preoperative irradiation has been undertaken in Toronto since 1961 (Bryce & Rider 1971) Therefore this clinical study gave us the opportunity to assess histopathologically the effect of irradiation in a series of patients treated with this mode of therapy Similar studies have been published in particular by Goldman and his associates (1961–1972).

Another main task was to use our material for a correlation between clinical and radiological evaluation and assessment, compared with our threedimensional histopathological study (Olofsson et al., 1973). This knowledge, we hoped, should ascertain the accuracy or inaccuracy of our methods of clinical examinations.

An ominous clinical sign in laryngeal carcinoma is the fixation of the vocal cord. The histopathological findings in such cases have been illustrated and a correlation has been made (in these cases) between our clinical assessment and the histopathological findings (Olofsson et al. 1973)

Through these studies we hoped to be equipped with a better understanding of the anatomy and of the growth and spread of laryngeal and hypopharyngeal carcinomas, and of the limitations in our clinical methods of assessment. Thereby we hoped to be able to better assess laryngeal and hypopharyngeal tumours and to select more accurately the patients suited for partial surgery

Neck dissections are not performed in all of our cases, but we thought that we at least should gain some information from those dissections that were performed.

60% of carcinomas arise in the piriform sinus, and the remainder are distributed equally between the postcricoid region and the posterior pharyngeal wall (MacComb & Fletcher 1967 Jørgensen 1971 Bryce 1972) An association between postcricoid carcinoma and Plummer Vinson syndrome has long been recognized (Ahlbom 1936 Jacobsson 1951 Wynder et al. 1957 Jones, 1961 Jørgensen 1971 Richards et al. 1971)

METHODS OF ASSESSMENT

A patient with a laryngeal or hypopharyngeal tumour should first be examined by indirect (mirror) laryngoscopy Following this the larynx and hypopharynx should be radiologically examined. Laryngeal tumours are investigated by soft tissue plain films, laryngeal tomography contrast laryngography and sometimes cinelaryngography Hypopharyngeal tumours and larger laryngeal tumour require also a barium swallow Then direct laryngoscopy (and/or hypopharyngoscopy) should be performed and, preferably the microlaryngoscopy technique described by Kleinsasser (1968) should be used. At the endoscopic procedures biopsy should be done to provide histologic confirmation of the diagnosis. Some surgeons recommend transconioscopy to assess subglottic extension of glottic tumours (Mårtensson et al. 1964 Mårtensson 1967 Sörensen 1970) Despite these various methods of clinical examinations there is still a great discrepancy between the clinical and radiologic findings and the true extent of the tumour growth (Fletcher et al. 1954 Ogura 1955 Tucker 1961 1963 Mårtensson 1967 Olofsson et al 1973)

METHODS OF THERAPY

It is generally accepted that early laryngeal carcinoma, particularly of the glottic region is best treated by primary radiotherapy with preservation of the larynx Surgery is reserved for irradiation failures in this group Some centres prefer laryngofissure and chordectomy for small glottic lesions (Zühlke & Schnepper 1968) The more advanced laryngeal lesions are treated either by primary surgery or by a combination of radiotherapy and surgery (Gisselsson & Lindgren 1952 Jackson et al. 1957 Voutilainen & Touvinen 1962 Bryce et al. 1963 Jackson & Norris, 1963 Silverstone et al 1963 Norris 1964 MacComb 1966 Skolnik, 1966 Holsti & Taskinen 1967 Lauerma 1967 MacComb & Fletcher 1967 Mårtensson et al. 1967 Rygård & Hansen 1967 Dahl et al 1968 Oeser 1968 Perez et al. 1968 Biller et al. 1969 Jørgensen, 1970 Ogura & Biller 1970 Vermund 1970 Bryce & Rider 1971 Jørgensen & Sell, 1971 Lederman, 1971 Morrison 1971 Bryce, 1972, Flynn et al. 1972 Goldman et al 1972)

No unanimity exists with respect to the treatment of hypopharyngeal carcinoma. In some centres at least all hypopharyngeal tumours are treated by primary radiotherapy (Jørgensen 1971 Ennuyer & Bataine 1972) and in others by primary surgery (Harrison 1966–1968) Still others use combined treatment (Biller et al 1969 Ogura & Biller 1970, Bryce, 1971 1972 Lalanne et al 1971 Lord et al 1972 Wang et al. 1972)

Some centres are afraid of giving radiotherapy to younger individuals with laryngeal carcinomas because they are concerned about late radiation changes including radiation induced carcinomas in long term survivors (Hayes et al. 1971)

AIMS OF THIS STUDY

The main purpose of this work was to achieve a better understanding of the growth and spread of laryngeal and hypopharyngeal carcinomas by studying laryngectomy and laryngopharyngectomy specimens by the method of whole-organ serial sectioning. The three-dimensional assessment thus achieved is far superior to the often inadequate sampling of such specimens in most routine laboratories. Our studies were directed to increasing our knowledge of the directional variability of the la

recommended retrograde laryngoscopy through the tracheostoma if tracheotomy had been performed for laryngeal obstruction. It is well established that histopathologically a tumour often has an extension that is much greater than can be assessed clinically (MacKenzie, 1900 McGavran et al., 1959 Norris, 1959- Tucker 1961 1963) Norris & Peale (1966), Goldman et al. (1966), Skolnik et al. (1970) have all demonstrated the difficulties involved in assessing the extension of the tumour espe cially after previous irradiation. Some oedema most often accompanies radiotherapy of la ryngeal carcinoma However in some patients the oedema is more prominent and persists for a long time or recur after the initial oedema has subsided Among these cases we can ex pect a high percentage of residual or recurrent carcinoma (Calcaterra et al 1972) Another problem in evaluation of postirradiation cases is that the tumour growth is often beneath an intact mucosa. Similar problems have been noted in our own series, and we ha e stressed particularly the difficulties in assessing the vertical but especially the deep extension of tumours even with the assistance of radiological in estigations (Olofsson et al 1973)

WHOLE-ORGAN SERIAL SECTIONING

In most centres the pathological examination of a laryngectomy specimen is poorly performed With little understanding of the anatomic rela tionships and their application in laryngeal sur gery the pathologist samples arious obvious area of tumour growth and issues a report Re ognizing the great deficiencies and lack of clinical practical value of such examinations, laryngologists ha e attempted for many years to develop better methods of laboratory a ses ment Leroux Robert (1936) was the first to use a method of whole-organ serial section ing Smitman (1945) serially sectioned paraffin embedded thyrotomy specimens. but did not pply the technique to the whole larynx. Ker nan (1950) embedded whole larynges in cel loid n for serial sectioning The M.D Ander son group (Fletcher et al. 1954 MacComb & Fletcher 1967) used a paraffin-embedding technique for the same purpose. Szlezak (1966) took whole organ serial slices from the tumour area which then were processed and embedded in paraffin. It was Tucker (1961) however who popularized the celloidin-embedding technique, which has been employed in a number of other laboratories (Goldman et al., 1964–1972 Kirchner 1969- Harrison, 1969- Delahunty & Nassar 1969 Skolnik, 1970). Hyams (1969) at the Armed Forces Institute of Pathology (A.F I.P) refined the paraffin embedding technique which we adapted for use in our own laboratory

GROWTH AND SPREAD

The systematic study of the growth and spread of laryngeal and hypopharyngeal carcinoma in the correlation with the anatomical land-marks has only been carried out since the development of whole organ serial sectioning technique (Leroux-Robert, 1936) Most of the studies performed since 1936 have been con-cerned with laryngeal rather than hypopharyn-geal tumours

Coutard & Valat (1927) noticed that supra-glottic carcinomas had specific characteristics. These tumours did not extend to the glottic region. They often crossed the anterior midline to occupy both sides The appearance was most often of the cauliflower" type. In his pioneer work in this field Leroux Robert (1936) em phasized that supraglottic tumours never ex tended towards the subglottic region He also observed that carcinomas of the ventricles often invaded the thyroid cartilage Smitman (1945), using the serial sectioning technique confirmed earlier studies, which suggested that carcinoma limited to the true vocal cord tended to grow to the anterior commissure and on to the opposite cord. He also demonstrated the value of the serial sectioning technique in revealing residual tumour at the resection margins of the specimen.

McKenty (1926) and Broyles (1943) sepa

Background Information

TERMINOLOGY

The more detailed study of laryngeal carcinoma was not possible until Garcia in 1854 introduced the indirect or mirror laryngoscopy technique (St. Clair Thomson 1939). In 1876 Isambert recommended that tumours in the subglottic region should be distinguished from other laryngeal tumours. In 1879 Krishaber divided tumour in the region into intrinsic laryngeal tumours and extrinsic laryngeal tumours. He classified tumours arising at the entrance of the larynx and the outer surface of the larynx as extrinsic and considered these to be more malignant. This terminology persisted for the next 50 years. In 1930 St. Clair Thomson and Colledge suggested four groups: intrinsic, subglottic, extrinsic and mixed. Already in 1937 Quick proposed a less conforming terminology. He divided the tumours in "cancer of the larynx" and "cancer of the hypopharynx". He considered however "cancer of the epiglottis" as a separate group. Walsh (1947) used the term "intrinsic" only for those tumours confined to a true vocal cord and not crossing the anterior commissure. He applied the term "endolaryngeal" to other tumours within the larynx except for the subglottic group. The fourth group was the extrinsic or extralaryngeal one.

Baclesse (1949) and Lederman (1952) divided laryngeal tumours into supraglottic, glottic and subglottic, and separated these from hypopharyngeal tumours. U.I.C.C. (Union Internationale Contre le Cancer) (1962) and the A.J.C. (American Joint Committee on Cancer Staging and End Results Reporting) (1962) accepted this terminology and further defined these anatomic areas, with minor variations. The supraglottic region includes the posterior (laryngeal) surface of the epiglottis, the ventricular bands and the ventricular cavities (sinuses). The tip of the epiglottis was excluded by the U.I.C.C. (1962) but this area was accepted as supraglottic by the A.J.C. (1962) and has also been accepted by the new U.I.C.C. classification (1972). The glottic region includes the vocal cords and the anterior and posterior commissures. The A.J.C. makes no mention of the posterior commissure area. The subglottic region extends to the lower border of the cricoid but excludes the under surface of the vocal cords.

Both the U.I.C.C. (1962) and the A.J.C. (1965) divide the hypopharyngeal area into three regions: piriform sinus, postcricoid and posterior pharyngeal wall.

Lederman (1970, 1971) divided the supraglottic region into two parts: the epilaryngeal (suprahyoid epiglottis, aryepiglottic folds and arytenoids) and the supraglottic (infrahyoid epiglottis, ventricles and false vocal cords).

Lederman (1970, 1971) also suggested dividing the subglottic region into two parts—one mobile and the other fixed. The upper mobile part is related to the conus elasticus and the thyroarytenoid muscles responsible for movement of the glottis, and the lower fixed part is related to the mucosa lining the cricoid ring.

ASSESSMENT DIFFICULTIES

Even though the clinician has many diagnostic tools with which to assess the extent of tumour growth, such assessments are frequently inaccurate. Mårtensson et al. (1964) and Mårtensson (1967) pointed out the difficulties to assess subglottic extension and recommended transconioscopy as a diagnostic tool. Clerf (1940)

recommended retrograde laryngoscopy through the tracheostoma if tracheotomy had been performed for laryngeal obstruction. It is well established that histopathologically a tumour often has an extension that is much greater than can be assessed clinically (MacKenzie 1900; McGavran et al. 1959; Norris, 1959; Tucker 1961, 1963). Norris & Peale (1966), Goldman et al. (1966), Skolnik et al. (1970) have all demonstrated the difficulties involved in assessing the extension of the tumour especially after previous irradiation. Some oedema most often accompanies radiotherapy of laryngeal carcinoma. However, in some patients the oedema is more prominent and persists for a long time, or recur after the initial oedema has subsided. Among these cases we can expect a high percentage of residual or recurrent carcinoma (Calcaterra et al. 1972). Another problem in evaluation of postirradiation cases is that the tumour growth is often beneath an intact mucosa. Similar problems have been noted in our own series, and we have stressed particularly the difficulties in assessing the vertical but especially the deep extension of tumours even with the assistance of radiological investigations (Olofsson et al., 1973).

WHOLE-ORGAN SERIAL SECTIONING

In most centres the pathological examination of a laryngectomy specimen is poorly performed. With little understanding of the anatomic relationships and their application in laryngeal surgery, the pathologist samples various obvious areas of tumour growth and issues a report. Recognizing the great deficiencies and lack of clinical practical value of such examinations, laryngologists have attempted for many years to develop better methods of laboratory assessment. Leroux-Robert (1936) was the first to use a method of whole-organ serial sectioning. Snitman (1945) serially sectioned paraffin embedded thyrotomy specimens, but did not apply the technique to the whole larynx. Kernan (1950) embedded whole larynges in celloidin for serial sectioning. The M.D. Anderson group (Fletcher et al., 1954; MacComb & Fletcher 1967) used a paraffin-embedding technique for the same purpose. Szlęzak (1966) took whole organ serial slices from the tumour area which then were processed and embedded in paraffin. It was Tucker (1961), however, who popularized the celloidin-embedding technique which has been employed in a number of other laboratories (Goldman et al., 1964–1972; Kirchner 1969; Harrison, 1969; Delahunty & Nassar 1969; Skolnik, 1970). Hyams (1969) at the Armed Forces Institute of Pathology (A.F.I.P.) refined the paraffin-embedding technique, which we adapted for use in our own laboratory.

GROWTH AND SPREAD

The systematic study of the growth and spread of laryngeal and hypopharyngeal carcinoma in the correlation with the anatomical landmarks has only been carried out since the development of whole organ serial sectioning technique (Leroux Robert, 1936). Most of the studies performed since 1936 have been concerned with laryngeal rather than hypopharyngeal tumours.

Coutard & Valat (1927) noticed that supraglottic carcinomas had specific characteristics. These tumours did not extend to the glottic region. They often crossed the anterior midline to occupy both sides. The appearance was most often of the "cauliflower" type. In his pioneer work in this field Leroux-Robert (1936) emphasized that supraglottic tumours never extended towards the subglottic region. He also observed that carcinomas of the ventricles often invaded the thyroid cartilage. Snitman (1945), using the serial sectioning technique, confirmed earlier studies, which suggested that carcinoma limited to the true vocal cord tended to grow to the anterior commissure and on to the opposite cord. He also demonstrated the value of the serial sectioning technique in revealing residual tumour at the resection margins of the specimen.

Background Information

TERMINOLOGY

The more detailed study of laryngeal carcinoma was not possible until Garcia in 1854 introduced the indirect or mirror laryngoscopy technique (St. Clair Thomson 1939) In 1876 Isambert recommended that tumours in the subglottic region should be distinguished from other laryngeal tumours. In 1879 Krishaber divided tumour in the region into intrinsic laryngeal tumours and extrinsic laryngeal tumours. He classified tumours arising at the entrance of the larynx and the outer surface of the larynx as extrinsic and considered these to be more malignant. This terminology persisted for the next 50 years. In 1930 St Clair Thomson and Colledge suggested four groups intrinsic subglottic, extrinsic and mixed Already in 1937 Quick proposed a less conforming terminology He divided the tumours in "cancer of the larynx and cancer of the hypopharynx He considered however "cancer of the epiglottis as a separate group Walsh (1947) used the term intrinsic only for those tumours confined to a true vocal cord and not crossing the anterior commissure He applied the term endolaryngeal to other tumours within the larynx except for the subglottic group The fourth group was the extrinsic or extralaryngeal one

Baclesse (1949) and Lederman (1952) divided laryngeal tumours into supraglottic, glottic and subglottic, and separated these from hypopharyngeal tumours. U I C C (Union Internationale Contre le Cancer) (1962) and the A.J C (American Joint Committee on Cancer Staging and End Results Reporting) (1962) accepted this terminology and further defined these anatomic areas, with minor variations. The supraglottic region includes the posterior (laryngeal) surface of the epiglottis, the ventricular bands and the ventricular cavities (sinuses) The tip of the epiglottis was excluded by the U I C.C. (1962) but this area was accepted as supraglottic by the A.J C. (1962) and has also been accepted by the new U I C.C. classification (1972) The glottic region includes the vocal cords and the anterior and posterior commissures. The A J C. makes no mention of the posterior commissure area The subglottic region extends to the lower border of the cricoid, but excludes the under surface of the vocal cords.

Both the U I C.C. (1962) and the A.J C. (1965) divide the hypopharyngeal area into three regions piriform sinus, postericoid and posterior pharyngeal wall.

Lederman (1970 1971) divided the supraglottic region into two parts the epilaryngeal (suprahyoid epiglottis, aryepiglottic folds and arytenoids) and the supraglottic (infrahyoid epiglottis ventricles and false vocal cords)

Lederman (1970 1971) also suggested dividing the subglottic region into two parts—one mobile and the other fixed. The upper mobile part is related to the conus elasticus and the thyroarytenoid muscles responsible for movement of the glottis, and the lower fixed part is related to the mucosa lining the cricoid ring

ASSESSMENT DIFFICULTIES

Even though the clinician has many diagnostic tools with which to assess the extent of tumour growth such assessments are frequently inaccurate. Mårtensson et al (1964) and Mårtensson (1967) pointed out the difficulties to assess subglottic extension and recommended transconioscopy as a diagnostic tool Clerf (1940)

the high frequency of pre-epiglottic space invasion by epiglottic tumors and the tendency of laryngeal tumours in general to invade the cartilaginous framework in the ossified portions of the cartilage

Harrison (1970) studied 50 hypopharyngeal tumours by whole-organ sectioning. He confirmed Hiroto's (1963) observation that piriform sinus and postericoid tumours commonly spread submucosally for 5 to 10 mm, and suggested that more radical resection would have controlled the primary disease in some of his patients.

Norris et al. (1970) studied 100 patients with laryngeal carcinoma treated surgically and correlated the findings with the results of a 5-year-follow-up These authors appreciated that the prognosis is much more predictable if one knows the depth of the penetration of the tumour as assessed histopathologically They stressed the need for a threedimensional concept in developing better methods of clinical and radiological evaluation.

Harrison (1971) emphasized that subglottic tumours produce ague symptoms initially and that they often are first recognized when they are extensive and produce dyspnoea, stridor or hoarseness (through invasion of intrinsic laryngeal muscles) He stressed the high frequency of paratracheal nodal involvement, and the clinically undetectable spread of these tumours to the trachea, hypopharynx and thyroid gland. He advocated wide-field excision *for such tumours*

Kirchner & Som (1971) studied 30 supraglottic tumours and indicated that exophytic lesions tend to remain above the laryngeal ventricle, and the anterior commissure, and that these tumours do not invade the thyroid ala Conversely ulcerative lesions may extend downward across the anterior commissure or anterior part of the ventricle and, in this case, frequently invade and destroy the anterior portion of the laryngeal framework. Of significance to the operating surgeon, microscopically these tumours did not invade the thyroid cartilage unless the inferior edge of the growth was visible below the level of the anterior commissure.

Nassar & Bridger (1971) and Bridger & Nassar (1971 1972) have suggested that the topography of the submucosal glands can influence spread of laryngeal carcinoma.

PREOPERATIVE RADIOTHERAPY

The aim of preoperative radiotherapy is to reduce local recurrence and to decrease the rate of metastasis. without delaying the operative procedures or slowing/preventing healing following surgery However preoperative irradiation delays definitive surgery but this delay is necessary for a proper administration of the radiation and for an optimal effect of the therapy (Powers & Palmer 1968 Moss & Brand, 1969). Earlier it was assumed that preoperative irradiation produces *fibrosis* and closes the lymphatic channels without changing the filtering function of the lymph nodes (*Cady 1968*). Animal studies by Engeset (1964) suggested a reduction in *filtering capacity* beginning two weeks after irradiation and continuing for 6 months.

Preoperative radiotherapy *is used in* preference to postoperative because after operation, oedema, scarring, and damage to the vascular bed may reduce tumour cell oxygenation, and it is known that poorly oxygenated *tumour cells* are less sensitive to irradiation (Nias, 1967 Moss & Brand, 1969 Coggle, 1971).

Animal experiments suggest that moderate doses of irradiation have little effect on the primary tumour but do decrease the "take" of transplanted cells (Hoye & Smith. 1961 Feder et al. 1963) and reduce the rate of local recurrence (Inch & McCredie, 1963). Studying tumours in mice Powers and Tolmach (1964) showed that preoperative radiotherapy (500 rads) increased the survival when *compared* with surgery alone.

Surgery combined with radiotherapy in the treatment of *laryngeal and* hypopharyngeal carcinomas has been used in many centres.

rately emphasized that early spread of laryngeal tumours tends to occur at the anterior commissure region Ogura (1955) confirmed this finding and further delineated the spread in this region especially noting that once the thyroid cartilage has been invaded spread occurs in all directions within the ossified portions of the cartilage

Baclesse (1949) made major contributions in several anatomic regions of the larynx and emphasized the value of radiologic studies in assessing the growth and spread of laryngeal tumours. He noted that, although tumours of the posterior end of the vocal cords were less common but when they were present they tended to invade the arytenoid and subglottic region earlier in their course and therefore had a bad prognosis. He also noted that supraglottic tumours (except for tumours of the ventricles) do not spread downwards, but that tumours of the glottis and ventricle frequently extended both up and down Thyroid cartilage invasion occurred most frequently in the middle third of the anterior part of the thyroid laminae The proximity between mucosa to cartilage in the depth of the ventricles could be enough to explain this He described the subglottic tumours as flat and irregular with submucosal spread and an ill-defined outline without showing the exuberant proliferation so often seen in supraglottic tumours

Ogura & Bello (1952) advocated prophylactic neck dissection and wide field laryngectomy in patients with fixed cord supra or subglottic involvement or tumours of the piriform sinus. In these cases, metastasis occur more frequently and may be present in impalpable lymph nodes.

In a major study Ogura (1955) studied 59 laryngectomy specimens with combined neck dissections The relationship between the invaded structures and nodal metastasis was tabulated. There was higher incidence of nodal metastasis in the extrinsic group—tumours arising from the base of the epiglottis, aryepiglottic folds, arytenoids and piriform sinuses than in the endolaryngeal tumours—those arising from the vocal cords, ventricles and false vocal cords. He noted a higher incidence of nodal metastasis if the endolaryngeal tumours invaded either the thyroid cartilage or the pre-epiglottic space regardless of the site of origin of the tumour

McGavran et al (1961) also related cervical nodal metastasis to certain characteristics of the primary tumour It was their impression that primary subglottic tumours were rare and that many so classified by other authors were in fact glottic tumour with subglottic extension There was a positive correlation between the frequency of nodal metastasis and poor differentiation of the tumour and nerve sheath invasion but not between nodal metastasis and vascular invasion. Tumours with "pushing margins tended to occur more frequently in the supraglottic region. Tumours with pushing margins had a lower frequency of nodal metastasis than tumours that were more infiltrating. The rate of nodal metastasis was highest in those tumours with a "transglottic distribution (crossing the ventricle occupying both the glottic and supraglottic regions) the rate was next highest in the supraglottic tumours, followed by the subglottic tumours.

Willis (1967) stated that glottic carcinomas first extend horizontally and then vertically He also indicated that the laryngeal cartilages act as physical barriers to tumour spread, and that the tumours usually penetrate the framework through the cricothyroid membrane

Bocca et al (1968) reported that in a study of 160 larynges totally removed for supraglottic tumours they had never observed that even very advanced lesions invaded the floor of the ventricle or the vocal cords

Kirchner (1969) in a review of 76 laryngeal tumours and 24 hypopharyngeal tumours studied by whole-organ sectioning reviewed the causes of vocal-cord fixation He noted that "transglottic tumours frequently invade the cricothyroid space and that supraglottic tumours tend to be less invasive but that piriform-sinus lesions frequently invade the thyroid ala He drew attention to two other features

Material and Methods

GENERAL

Whole-organ serial sectioning provides a unique method for studying the growth pattern and method of spread of laryngeal and hypopharyngeal carcinomas. By using this method of study we hoped to enhance our knowledge of these lesions, and thereby improve their clinical management.

In Toronto most laryngeal and hypopharyngeal carcinomas are treated by primary radiotherapy. The smaller lesions (T1 and T2) receive radiotherapy alone and surgery is employed for irradiation failure. The larger tumours (T3 and T4) in our series received preoperative radiotherapy followed by surgery either immediately or six weeks later. Primary surgery was reserved for a few small tumours managed by partial laryngectomy, for verrucous carcinomas, and for some large bulky tumours which produced airway obstruction. About 100 new laryngeal and 30 new hypopharyngeal carcinomas are seen every year in Toronto.

Since the latter part of 1966, when we began collecting laryngectomy and laryngopharyngectomy specimens from patients with laryngeal and hypopharyngeal carcinoma for whole organ serial sectioning, we have collected 153 specimens from 149 patients. Of these, 139 had squamous-cell carcinoma. Of this total only 3 were obtained at autopsy, the remainder were operative specimens. Two specimens were acquired from each of 4 patients, who first underwent partial laryngectomy and subsequently had a total laryngectomy. This report will describe the findings in 139 squamous-cell carcinomas of the larynx and hypopharynx.

The remaining 10 tumours of the series were made up of 4 squamous-cell carcinomas of the upper esophagus, and 1 of the oro-pharynx. There was 1 adenoid cystic carcinoma arising from the subglottic region, 1 adenocarcinoma of the thyroid gland and 2 hypopharyngeal fibrosarcomas. These last two tumours were reported separately (Bradshaw & van Nostrand, 1971). One anaplastic small-cell carcinoma of the larynx was studied and has also been separately reported (Olofsson & van Nostrand, 1972). Most patients in this series have been assessed and the treatment planned in a combined radiotherapy – otolaryngology clinic. After this, radiological examinations have been performed. In all treatment groups (including the preoperative radiotherapy group) reassessment of the tumour extension has always been done before surgery.

Laboratory technique

All specimens in the laboratory were opened, usually dorsally photographed and carefully described. A drawing was then made of each specimen.

Before 1970 the laryngectomy specimens were processed using the celloidin embedding technique described by Tucker (1961). The sections thus obtained were found to be too thick (approximately 25 μ) for an autoradiographic study being done concurrently on the same specimens (Briant et al., 1971). Accordingly we have used a paraffinembedding, subserial, sectioning technique on all specimens since late 1969. This technique which differs little from the standard paraffin sectioning method used in most routine anatomic pathology laboratories, is a modification of the method used in the Otolaryngological Laboratory at the Armed Forces Institute of Patho-

The radiotherapy can be administered post operatively (Leroux Robert 1956 Pietrantoni & Flor 1958 MacComb & Fletcher 1967 Fletcher et al. 1970) Pre and postoperative administration of the radiotherapy the so-called "sandwich method, has also been used (Leroux Robert 1956 see also Goldman et al 1964) Preoperative irradiation is, however the most common method (Goldman & Silverstone 1960 1961 Silverstone et al. 1963 Bryce, 1964 Goldman et al 1964–1972 McGavran et al. 1964 Powers & Ogura, 1965 Skolnik et al. 1966 1968, 1970 Goldman 1967 Biller et al. 1969 Ogura & Biller 1970 Bryce & Rider 1971 Levitt et al. 1971 Roswit et al 1972)

Many centres have used full dose (5 000–7 000 rads) preoperative irradiation. Goldman and his group in New York improved their results by giving elective preoperative irradiation in advanced cancer of the larynx and hypopharynx (Goldman & Silverstone 1960 1961 Silverstone et al 1963 Goldman et al 1964–1972 Goldman 1967 Goldman & Friedman 1969) This group uses 5 500–6 000 rads Cobalt 60 over 5–6 weeks, followed by radical surgery 3–6 weeks after completion of the radiotherapy Constable et al. 1972 also report improved results with this mode of therapy

On the other hand, Bryce & Rider of Toronto (1971) using an identical mode of therapy for advanced laryngeal carcinoma found no improvement in the 3 year survival rate when they compared this therapy with primary surgery and surgery for irradiation failure control group These authors concluded ever that irradiation therapy could be to divide patients with advanced lary cancer into those who required early and cal excision for control of their disease those for whom excision of the primary l will probably not be needed Wang e (1972) gave 4 500 rads to advanced supragl and piriform sinus lesions with borderline ability If the tumour showed satisfactory gression after this dose the radiation the was continued to curative dose and sur was reserved for radiation failure. Howeve the tumour did not respond well the comb radiation—surgery plan was followed

A number of other centres have used m smaller doses of preoperative irradia (1 500–3 000 rads) given 1–4 weeks prio surgery Hendrickson & Liebner (1968) fo no difference when they compared the res in treating advanced supraglottic carcin by 2 000 rads or 5 000 rads preoperatively noticed an improvement in comparison earlier primary surgery Most other cen using the smaller dose of irradiation 1–4 we prior to surgery have produced inconclu results regarding improved prognosis (McG ran et al. 1964 Powers & Ogura, 1965 H son & Cavanaugh 1965 Roswit et al 19 Biller et al. (1969) and Ogura & Biller (19 noticed a decrease in local recurrence of b of tongue and piriform sinus carcinoma w a low dose of preoperative irradiation.

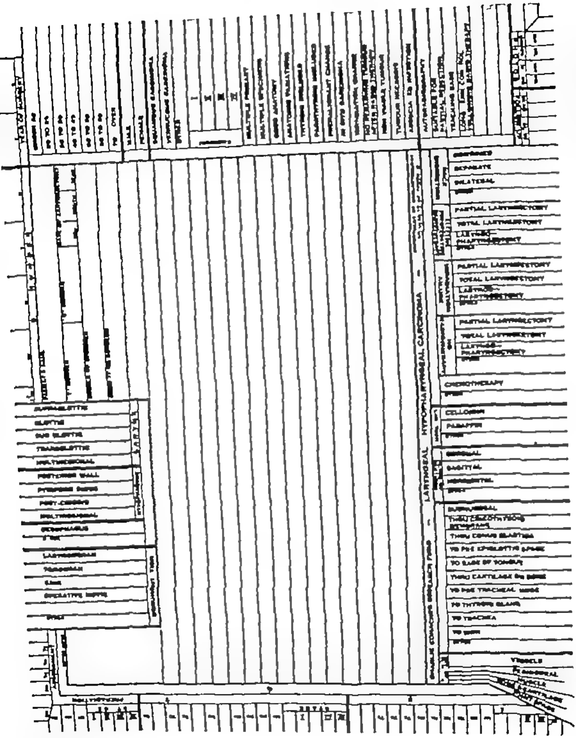

Fig. 1. Punch card used to record various histopathologic findings on each case. Ruled central portion is used for recording clinical data.

logy (Hyams, 1969) and is very similar to the technique used by the M D Anderson Hospital Laboratory for the same purpose (MacComb & Fletcher 1967) The main difficulties with this technique lie in the increased technical skill needed to section bone cartilage and soft tissues in a block of material the size of the human larynx Much credit for the development of the technique must go to the highly skilled technologists in our own laboratory whose dedicated work contributed much to the *development of this method A superior* celloidin paraffin double-embedding technique has recently been developed (Ekem 1972)

The bulk of the laryngeal tumours were sectioned in a coronal plane, because this provides more histopathologic information and correlates well with the preoperative radiographic studies *(Olofsson et al. 1973)* Epiglottic tumours were mainly sectioned in a sagittal plane For hypopharyngeal tumours horizontal sectioning gives more information

The histopathologic features of our cases have been tabulated on a punch card sortable by needle (Fig. 1) The use of this card has allowed easy access to readily correlatable features. The pertinent clinical data is typed into the central lined area.

Incidence

Of the 139 squamous-cell carcinomas in this series, *110 were primary laryngeal tumours,* and 29 were primary hypopharyngeal tumours.

Sex (Diagram I II)

Only 7 of the 110 laryngeal tumours occurred in females a ratio of approximately 15 1 male over female Of the 29 hypopharyngeal carcinomas, *only 8 occurred in females. Of the* 19 patients with piriform sinus tumours only 2 were females, whereas 4 of the 7 postcricoid tumours and 2 of the 3 multiregional tumours occurred in women

Comments The 15 1 male – female ratio in our series of laryngeal tumours is higher than in many other reported series (Wynder et al. 1956 Ackerman & del Regato 1970 National Board of Health and Welfare The Cancer Registry in Sweden 1971) All of our patients *had advanced or recurrent* carcinoma and all underwent surgery Thus our series is highly selected. With respect to the hypopharyngeal tumours, the ratio of male over female is 2.6 1 A male predominance is in keeping with other reported series (Ackerman & del Regato 1970 Jørgensen 1971) However Jacobsson *(1951) in a series of 322 patients had* 203 women and The National Board of Health and welfare The Cancer Registry in Sweden (1971) reports a ratio of male over female 1 3 1 (crude) in a review of 446 hypopharyngeal carcinomas. The higher frequency of females in the postcricoid group which has been reported by others may be related to the Plummer Vinson (or Paterson-Brown-Kelly) syndrome (Ahlbom 1936 Jacobsson 1951 Wynder et al 1957 Jones, 1961 Ackerman & del Regato 1970 Richards et al. 1971) although this diagnosis was never established in any of the patients in our series

Age (Diagram I II)

At the time of diagnosis the ages of the 110 patients with laryngeal tumours varied from 37 to 83 years with a mean of 59 years for the men and 63 for the women. As diagram I shows the peak incidence was between 50 and *69 years (71 %) Twenty-one patients were* 70 years or older and only 18 were under 50 The tumours in women appear to be fairly evenly distributed through the span 57–83 years.

Patients with hypopharyngeal tumours ranged in age from 42 years to 75 years, with a mean of 59 years for the men and 60 years for the women As with laryngeal tumours, the peak incidence in patients with hypopharyngeal tumours lies between 50–69 years.

Comment The age distribution in this series agrees *with that* described by other authors both for laryngeal tumours *(Pietrantoni & Flor* 1958 McGavran et al 1961 Lauerma 1967

complications after a laryngopharyngectomy There was no residual or metastatic tumour at autopsy The smoking habits of this patient are unknown.

The other patient developed a multiregional carcinoma, probably of piriform-sinus origin, 54 years after radiotherapy for thyroid disease This patient was a non-smoker

Comment Irradiation-induced tumours are well recognized and both epithelial tumours, e.g. basal-cell carcinoma, squamous-cell carcinoma and thyroid carcinoma, and mesenchymal tumours, e.g. osteogenic sarcoma, chondrosarcoma, fibrosarcoma and leukemias have been described (Ackerman & del Regato 1970).

Squamous-cell carcinomas of the larynx and hypopharynx have been described following irradiation for pre-existing benign or malignant processes (Goolden 1951 1957 Holinger & Rabbett, 1953 Som & Peimer 1955 Baker & Weissman 1971 Cronin, 1971 Stell, 1971 Schindel & Castoriano 1972) The latent period between the irradiation and the diagnosis of carcinomas was usually 20 to 35 years.

LARYNGEAL CARCINOMA (110 CASES)

Histologic grading

Using Broders classification (Broders, 1932) all the tumours were graded in terms of degree of differentiation (Table I). In all cases, to avoid the changes produced by irradiation therapy the grading was performed on the original biopsy Nine tumours were classified as Grade I and of these 4 were verrucous carcinomas These 4 have been separately reported (van Nostrand & Olofsson, 1972). Of these 9 tumours, 6 were glottic and 3 were supraglottic.

The vast majority of the tumours, 87 were classed as Grade II Sixty of these were glottic, 18 were supraglottic, 3 were subglottic and 6 were of the very large tumours, classified as multiregional.

Twelve tumours were classed as Grade III and of these 7 were glottic, 3 were supraglottic, and 2 were multiregional.

Grade IV tumours were very uncommon we encountered only 2. One of these was supraglottic and the other subglottic.

Comment Most of the tumours in this study were moderately well differentiated lesions. If one excluded the verrucous group, only 7 tumours (5 Grade I and 2 Grade IV) lie at the extremes of differentiation. While Jackson & Jackson (1939 1945) indicated that a biopsy specimen may not necessarily reflect the differentiation of the whole tumor McGavran et al. (1961) found little difference between the biopsies and the excised tumours in a large series of cases A greater proportion of the supraglottic tumours were in the poorly differentiated range. This finding may partially explain the worse prognosis of these tumours.

Taskinen 1969 The National Board of Health and Welfare, The Cancer Registry in Sweden 1971) and for hypopharyngeal tumours (Jacobsson 1951 Pietrantoni & Fior 1958 The National Board of Health and Welfare The Cancer Registry in Sweden 1971).

Etiologic factors

Smoking and alcohol

Cigarette smoking is a significant factor in the causation of laryngeal cancer in men (Wynder et al. 1956 Stell 1971 1972) We have information regarding the smoking habits of 92 of the 110 patients with laryngeal carcinoma. Only 5 were nonsmokers. One patient smoked cigars and 7 smoked pipes. The remaining 79 smoked cigarettes, and 65 of these smoked in excess of 20 cigarettes daily usually for many decades. The smoking habits of 5 of the 7 women were known All 5 were cigarette smokers, and 4 smoked in excess of 20 cigarettes daily

Smoking habits are known in 23 out of the 29 patients with hypopharyngeal carcinoma Nineteen were smokers—17 smoked cigarettes, 1 smoked a pipe and 1 smoked cigars Eleven of the cigarette smokers smoked in excess of 20 cigarettes daily Of the 4 non smokers, 3 were female and 1 was male

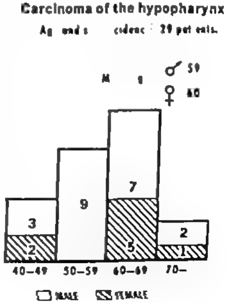
Excessive consumption of alcohol was noted in both laryngeal and hypopharyngeal tumours, particularly in the heavy smoking group.

Comment The association of both excess smoking and alcohol intake with laryngeal and hypopharyngeal carcinomas has been well documented previously (Jacobsson 1951 Wynder et al 1956 1957 Dunn & Dykstra, 1967 MacComb & Fletcher 1967 Sirala & Sirala 1967 Ackerman & del Regato 1970 Stell, 1971 1972)

Ryan et al (1955) Zechner (1968) and Auerbach et al (1970) demonstrated positive correlation between laryngeal mucosal changes and duration and amount of cigarette smoking habits. Poor oral hygiene and low social standard are other factors of importance but have not been especially reviewed in our series.

Irradiation

Two of the patients with hypopharyngeal carcinomas had previous irradiation to the neck area One of these a woman (Table XV) developed a piriform sinus carcinoma 30 years after radiotherapy for thyrotoxicosis. This tumour was successfully treated by radiotherapy Nine years later at the age of 76 she developed a postericoid carcinoma and died of surgical



Diagram

complications after a laryngopharyngectomy There was no residual or metastatic tumour at autopsy The smoking habits of this patient are unknown

The other patient developed a multiregional carcinoma, probably of piriform-sinus origin, 54 years after radiotherapy for thyroid disease. This patient was a non-smoker

Comment. Irradiation-induced tumours are well recognized and both epithelial tumours e.g. basal-cell carcinoma, squamous-cell carcinoma and thyroid carcinoma, and mesenchymal tumours, e.g. osteogenic sarcoma, chondrosarcoma, fibrosarcoma and leukemias have been described (Ackerman & del Regato, 1970).

Squamous-cell carcinomas of the larynx and hypopharynx have been described following irradiation for pre-existing benign or malignant processes (Goolden, 1951 1957 Holinger & Rabbett, 1953 Som & Peimer 1955 Baker & Weissman 1971 Cronin 1971 Stell, 1971 Schindel & Castoriano, 1972). The latent period between the irradiation and the diagnosis of carcinomas was usually 20 to 35 years

LARYNGEAL CARCINOMA (110 CASES)

Histologic grading

Using Broders classification (Broders, 1932) all the tumours were graded in terms of degree of differentiation (Table I) In all cases, to avoid the changes produced by irradiation therapy the grading was performed on the original biopsy Nine tumours were classified as Grade I and of these 4 were verrucous carcinomas. These 4 have been separately reported (van Nostrand & Olofsson, 1972). Of these 9 tumours, 6 were glottic and 3 were supraglottic.

The vast majority of the tumours, 87 were classed as Grade II Sixty of these were glottic, 18 were supraglottic, 3 were subglottic and 6 were of the very large tumours, classified as multiregional.

Twelve tumours were classed as Grade III and of these 7 were glottic, 3 were supraglottic, and 2 were multiregional.

Grade IV tumours were very uncommon we encountered only 2. One of these was supraglottic and the other subglottic.

Table I *Histologic grading of laryngeal carcinomas (Broders')*

	I	II	III	IV	Total
Supraglottic	3 (1)[a]	18	3	1	25
Glottic	6 (3)[a]	60	7		73

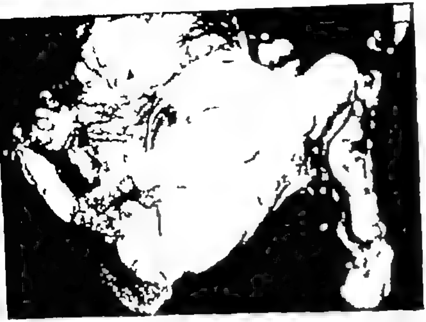
(*d* + *h*) Glottic tumour with marked supraglottic extension.

Site of origin and anatomic distribution (Table II)

In defining the site of origin of the tumours in this series, we have used the basic criteria laid down in the U I C C (1962) system. We are well aware of the fact that this classification is based on clinical and radiological examinations and cannot be directly transferred into a histopathological study. This present histopathologic study takes the conus elasticus as the structure separating the glottic and the subglottic region in keeping with the boundaries proposed by Lederman (1970, 1971). We have considered the lateral angle of the ventricle to be the boundary between the glottic and supraglottic regions (Fig. ?). Clinically, it has always been difficult to establish the site of origin of laryngeal tumours, but in most cases it is much less difficult to assess the site of origin in serially sectioned operative specimens. However, in large tumours which occupy several anatomic regions, classification may still be difficult. McGavran et al. (1961) used



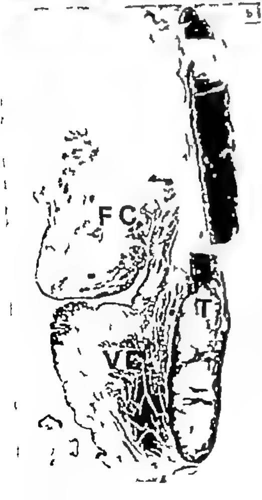


Fig. 3. Glottic tumour confined to glottic region. This patient was treated by radiotherapy (5 500 rads Cobalt 60). Partial laryngectomy was performed 14 months later for irradiation failure.

(a) Right fronto-lateral partial laryngectomy specimen. The arrow indicates the small localized tumour at the junction of the anterior and middle third of the vocal cord.

(b) Coronal section of the specimen taken at the level indicated by the arrow in a. The tumour is confined to the free margin of the vocal cord. FC = false vocal cord, T = thyroid ala; VC = vocal cord.

the term "transglottic tumour" to describe a tumour which spread across the laryngeal ventricle to involve both the glottic and supraglottic regions.

Of the 110 cases in this series (see Table II), 73 were primary glottic tumours. Thirteen of these were confined to the glottic region (Figs. 2 *a* and 3), 24 had extended to the subglottic region (Figs. 2 *b* and 4), 5 had extended to the supraglottic region (Figs. 2 *c*, 2 *d* and 27) and 31 had extended to both the supraglottic and subglottic regions (Figs. 2, 7–11, 29). (Sixteen of the tumours in this group would have been classified as "transglottic" by other authors (McGavran et al. 1961, Kirchner 1969).)

Twenty-five tumours arose in the supraglottic region. Eleven of these were confined to the supraglottic region (Figs. 12, 13), but

Fig 4 Glottic tumour with subglottic extension This patient was treated by radiotherapy (1 000 rads Cobalt 60) one day prior to total laryngectomy
( ) Gross photo of the laryngectomy specimen There is a large ulcerated tumour occupying the full length of the right vocal cord with subglottic extension.

(b) Coronal section through the anterior third of the vocal cords. The tumour (as outlined by arrows) occupies the right glottic region and has extended subglottically C = cricoid cartilage FC = false vocal cord T = thyroid ala VC = vocal cord.

two included tip of epiglottis (T4 according to U I C.C 1962) 5 had extended to the glottic region (Figs. 14 15) 5 had extended to the oropharynx 3 had extended to the hypopharynx, and one to glottic region oropharynx and hypopharynx.

Of these 110 tumours 4 arose in the subglottic region and all 4 extended through the *conus elasticus to involve the glottic region* (Figs. 16 17)

Eight of these tumours were so large that they defied accurate assessment and hence were classed as *multiregional (Figs. 18–20) In* all probability 6 of these arose in the glottic region All of these tumours would be considered "transglottic" by other authors, thus *24 tumours in the entire series of 110 tumours* (22%) would have been so considered.

Comment It has been generally accepted that primary supraglottic tumours tend to have pushing margins and virtually never extend into the glottic regions (Coutard & Valat, 1927 Leroux Robert, 1936 Baclesse 1949 Bocca, 1968 Kirchner & Som 1971)

As a result of this observation horizontal supraglottic partial laryngectomy has been *liberally employed in the management of primary* supraglottic carcinomas. However in the present series, 6 of the 25 primary supra glottic tumours (24%) had extended below the *ventricle into the glottic region* (Figs. 14 15)

Szlęzak (1966) made the same observation in his series of serially sectioned specimens. 10 of his 25 supraglottic tumours extended below the ventricle The supraglottic extension of primary glottic tumours, which was much

more common, was observed in 36 of 73 cases (49%) (Figs. 7–11 27 29).

Our number of transglottic tumours 22% (24/110) corresponds well to Kirchner's (1969) figure of 25% (19/76) Many authors suggest that many of these tumours originate in the laryngeal ventricle (Leroux-Robert, 1936 Baclesse, 1949 Kirchner 1969· Ackerman & del Regato 1970)

We believe that tumours originating in the ventricular cavities (sinuses) must be extremely rare. Ogura (1955) classified only 1 of his 43 laryngeal carcinomas as ventricular The laryngeal ventricle is normally lined by ciliated columnar (respiratory) epithelium, and only in a small number of patients who have had radiotherapy to this region have we seen this epithelium change to squamous epithelium. Since squamos carcinoma must arise from squamous epithelium, it seems less likely that such a tumour would arise from the ventricle. Furthermore we have never observed dysplasia of the metaplastic squamous epithelium that is occasionally seen in the ventricle in our post irradiation cases. Finally we have examined a number of autopsy larynges by serial sectioning techniques, and have never observed squamous metaplasia of the ventricular mucosa, not even in those cases with severe dysplasia of the free margin of the vocal cords or false vocal cords.

Fig 5 Spread through the cricothyroid membrane Coronal section through the anterior commissure region of total laryngectomy specimen showing how the tumour (marked by arrows) spreads through the cricothyroid membrane and destroys the lower margins of the thyroid cartilage. This patient had glottic tumour with subglottic extension which was treated by radiotherapy (5 500 rads Cobalt 60) Four and one half months later total laryngectomy and left neck dissection as performed for irradiation failure. C cricoid cartilage· T = thyroid ala.

Clinical management (Table III)

As indicated earlier our patients fell into three broad therapeutic categories: those treated by primary surgery· those having salvage surgery for irradiation failure and those having elective surgery following radiotherapy The 3 patients who came to autopsy are considered separately

Primary surgery

Eighteen patients were treated by primary surgery Of these, 10 had total laryngectomy—5 had primary glottic (Fig. 7), 2 had supraglottic (Figs. 14 15), and 3 had multiregional tumours (Fig. 19). In 5 of these 10 patients, the procedure included a block dissection of the neck (in 1 it was bilateral). Four of these 5 patients had metastatic tumour in cervical lymph nodes. The glottic primary with bilateral

Fig 4 Glottic tumour with subglottic extension This patient was treated by radiotherapy (1 000 rads Cobalt 60) one day prior to total laryngectomy

(*a*) Gross photo of the laryngectomy specimen There is a large ulcerated tumour occupying the full length of the right vocal cord with subglottic extension.

(*b*) Coronal section through the anterior third of the vocal cords. The tumour (as outlined by arrows) occupies the right glottic region and has extended subglottically C = cricoid cartilage FC = false vocal cord T = thyroid ala VC = vocal cord.

two included tip of epiglottis (T4 according to U I C C 1962) 5 had extended to the glottic region (Figs. 14 15) 5 had extended to the oropharynx 3 had extended to the hypopharynx and one to glottic region, oropharynx and hypopharynx.

Of these 110 tumours 4 arose in the subglottic region and all 4 extended through the conus elasticus to involve the glottic region (Figs. 16 17)

Eight of these tumours were so large that they defied accurate assessment and hence were classed as multiregional (Figs. 18–20) In all probability 6 of these arose in the glottic region All of these tumours would be considered transglottic by other authors, thus 24 tumours in the entire series of 110 tumours (22 %) would have been so considered.

Comment It has been generally accepted that primary supraglottic tumours tend to have pushing margins and virtually never extend into the glottic regions (Coutard & Valat 1927 Leroux Robert 1936 Baclesse 1949 Bocca, 1968 Kirchner & Som 1971)

As a result of this observation, horizontal supraglottic partial laryngectomy has been liberally employed in the management of primary supraglottic carcinomas. However in the present series, 6 of the 25 primary supraglottic tumours (24 %) had extended below the ventricle into the glottic region (Figs. 14 15)

Szlęzak (1966) made the same observation in his series of serially sectioned specimens. 10 of his 25 supraglottic tumours extended below the ventricle. The supraglottic extension of primary glottic tumours, which was much

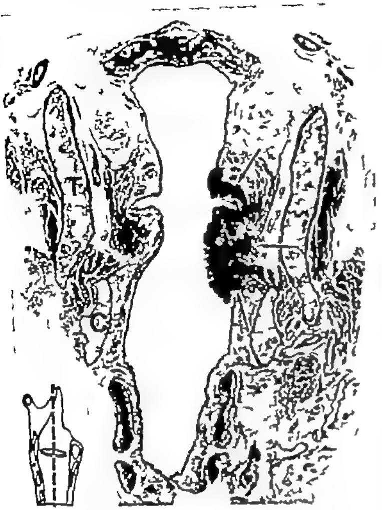

Fig. 7. Glottic tumour with subglottic and slight supraglottic extension. Coronal section through the middle one third of the vocal cords (small diagram indicates the plane of the section). This glottic tumour (as outlined by arrows) has extended subglottically through the conus elasticus, and has also extended around the laryngeal ventricle into the supraglottic region. This patient was treated by primary total laryngectomy. C = cricoid cartilage, E = epiglottis, T = thyroid ala.

Table III. *Clinical management — laryngeal carcinoma (110 patients)*

	Primary surgery		Irradiation failure		Combined therapy: 5 500 Rads		Combined therapy: 500–2 000 R	Autopsy cases
	Total	Partial	Total	Partial	Total	Partial	Total	
Glottic	5	4	25	8 (2)	23		6	2

Neck dissection 50 (22)	5 (4)	1 (1)	15 (6)	0	23 (7)	0	5 (3)	1 (1)

[a] One patient had partial laryngectomy for a verrucous carcinoma of the epiglottis and later had a total laryngectomy because of aspiration. There was no residual tumour in the total laryngectomy specimen.
[b] Two patients had partial laryngectomies followed by total laryngectomy for recurrent tumour.
[c] One patient had partial laryngectomy and later had a total laryngectomy because of inability to swallow. There was no residual tumour in the total laryngectomy specimen.

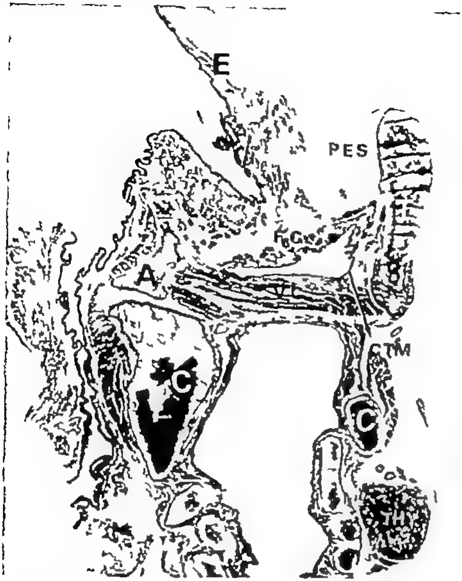

Fig 6 Route of spread through the cricothyroid membrane Sagittal section of a normal larynx taken close to the midline Tumours involving the anterior commissure region often extend through the cricothyroid membrane (CTM) but in order to do so the tumour must first extend subglottically (Route marked by arrow) A = arytenoid cartilage C = cricoid cartilage E = epiglottis FC = false vocal cord PES = pre-epiglottic space T = thyroid cartilage THY = thyroid gland VC = vocal cord

neck dissections had metastasis to nodes on both sides. Patients with advanced carcinomas, who often had airway obstruction and/or nodal metastasis were treated by primary total laryngectomy

Eight patients were treated by primary partial laryngectomy—4 of these had horizontal supraglottic laryngectomies (Fig 13) 3 had partial vertical laryngectomies and 1 had laryngofissure with cordectomy The 4 horizontal supraglottic laryngectomies were performed for supraglottic tumours 1 of these patients had a combined neck dissection with positive nodes. The remaining 4 tumours were confined to the glottic region and neck dissection was not performed

One patient should be singled out (see Table III) This 77 year-old woman had an extensive verrucous carcinoma of the epiglottis, which was treated by a horizontal supraglottic laryngectomy Four months later a total laryngectomy was performed because she was aspirating saliva and food. We found no residual tumour in the total laryngectomy specimen This case has been separately reported (van Nostrand & Olofsson 1972)

Salvage surgery for irradiation failure

Forty six patients in the series underwent surgery for residual or recurrent tumour after radiotherapy with occasional exceptions they received Cobalt 60 in a dosage of 5 500 rads The interval between radiotherapy and operation varied from 2 months to 87 months (7

F g 7 Glottl tumour with subglott and slight supraglottic extension Coronal section through the middle one third of the ocal cords (small diagram indicates the plane of the sec tion) This glottic tumour (as outlined by arrow) has extended subglottically through the conus elasticus, and has also extended around the laryngeal entricle into the supraglottic region. This patient was treated by primary total laryngectomy C = cricoid cartilage E = epiglottis, T = thyroid ala

Table III *Clinical management — laryngeal carcinoma (110 patients)*

One patient had partial laryngectomy for errucous carcinoma of the epiglottis and later had a total laryngectomy because of aspiration There was no residual tumour in the total laryngectomy specimen
Tw patients had partial laryngectomies followed by total laryngectomy for recurrent tumour
One patient had partial laryngectomy and later had a total laryngectomy because of inability to swallow There as no residual tumour in the total laryngectomy specimen.

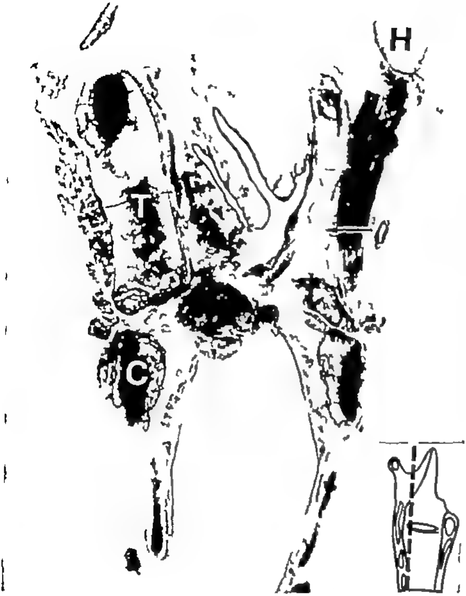

Fig 8 Glottic tumour with subglottic and slight supraglottic extension Coronal section through the anterior commissure region of a total laryngectomy specimen The tumour involves mainly the left vocal cord and anterior commissure region and has extended subglottically In other sections from the specimen slight supraglottic extension was also present. Seven years previously this patient had radiotherapy (5 500 rads Cobalt 60) for a tumour of the right vocal cord. Two years later an extended laryngofissure with removal of the anterior portion of the right thyroid ala was performed (arrow denotes absent right ala) Note that the recurrent tumour was mainly at the anterior commissure and on the left side of the specimen C = cricoid cartilage H = hyoid bone T = thyroid ala.

years and 3 months) with the median interval being 18 months.

Thirty-six of these 46 patients were treated by total laryngectomy—25 had primary glottic tumours (Figs. 8 10 11) 5 had primary supraglottic tumours, 3 had subglottic tumours (Figs. 16 17) and 3 had multiregional lesions (Figs. 18 20) Of these 36 15 had combined neck dissection—six had positive lymph nodes (all three of the patients with supraglottic tumours who had neck dissection had positive nodes) One patient with a supraglottic carcinoma had bilateral neck dissection, one of which contained metastatic lymph nodes.

Two patients deserve special mention (Table III) One received radiotherapy for a glottic carcinoma but developed a recurrence two years later which was treated by extended

Fig. 9. Glottic tumour with prominent subglottic and very high supraglottic extension. Coronal section through the middle third of the vocal cords, showing tumour occupying both vocal cords with large subglottic extension. The arrows indicate the strikingly sharp superior margin of the tumour. Note also the extensive invasion of the lower one half of both thyroid alae. This tumour also spread outside the laryngeal framework through the cricothyroid membrane and the cricothyroid spaces bilaterally. This patient received 500 rads Cobalt 60 just prior to total laryngectomy. C = cricoid cartilage, E = epiglottis, T = thyroid ala.

laryngofissure. Five years after this operation, a total laryngectomy was performed for a recurrent tumour in the anterior commissure (new) and on the anterior portions of the opposite vocal cord (Fig. 8). The other patient received irradiation for a glottic carcinoma in the region of the vocal process. Six months later a recurrent tumour was treated by a partial vertical laryngectomy. One year later a total laryngectomy was performed for recurrent tumour involving the homolateral hemilarynx.

In 10 other patients, partial laryngectomy was performed for residual or recurrent tumour. None of these had a neck dissection. The primary tumour was glottic in 8 and these were treated by vertical partial laryngectomy (Fig. 3). One patient had a supraglottic

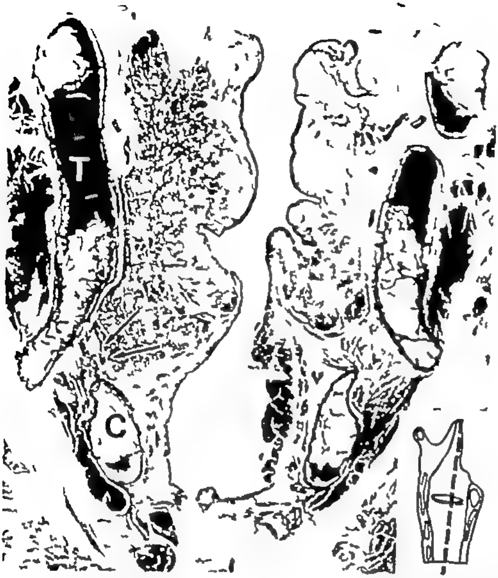

Fig 10 Glottic Tumour with supraglottic and subglottic extension ("transglottic") Coronal section through the middle third of the vocal cords. On the left side the tumour has a transglottic distribution. Arrows indicate the tendency for this tumour to spread through the cricothyroid space. On the right side the tumour occupies the vocal cord. There is also very marked surface extension of tumour into the subglottic region. This patient first received radiotherapy (5 500 rads Cobalt 60) for a left glottic tumour with slight subglottic and supraglottic extension. Two years later a total laryngectomy was performed for recurrent tumour. C = cricoid cartilage T = thyroid ala.

primary treated by horizontal supraglottic laryngectomy. An additional supraglottic primary tumour had spread to the glottic level and was treated by partial vertical laryngectomy.

Combined therapy (elective surgery following radiotherapy)

As a pilot study begun in this centre in 1961 a series of patients with hypopharyngeal and large laryngeal carcinomas were treated by

Fig 11 Extensive tumour beneath intact mucosa (postirradiation). Three years before laryngectomy this patient had radiotherapy (5 500 rad Cobalt 60) for a tumour occupying the right vocal cord. Because of the development of vocal cord fixation direct laryngoscopy was performed. One of the four blind biopsies taken contained tumour.

(*a*) Gross photograph of the laryngectomy specimen showing slight ulceration of mucosa at the anterior commissure and subglottically on the right side at the site of the previous biopsy.

(*b*) Coronal section through the middle third of the vocal cords illustrating large tumour extension

beneath mainly intact mucosa. The tumour is ade both supraglottically and subglottically. Note invasion of the thyroid cartilage (T) and cricoid cartilage (C). Arrow indicates tumour outside the thyroid ala. E epiglottis.

( ) Coronal section through the arytenoid region showing extensive tumour lateral to the arytenoid cartilage (A), invasion of the arytenoid and cricoid cartilages, and of the right cricothyroid joint. Note overlying intact mucosa. The arrow indicates tumour spread outside the thyroid ala.

(*d*) Coronal section through the posterior plate of the cricoid cartilage. The tumour invades the right cricoarytenoid joint and adjacent parts of the arytenoid and cricoid cartilages. Note also the invasion of the posterior cricoarytenoid muscle (arrow).

Fig 17 Tumour of the tip of the epiglottis. Five years prior to the present surgery this patient received radiotherapy (5 500 rads Cobalt 60) for a left vocal cord carcinoma. He developed a new primary at the tip of the epiglottis, treated by horizontal supraglottic partial laryngectomy

(*a*) Specimen viewed from the laryngeal surface showing the ulcerated tumour at the tip of the epiglottis.

(*b*) Sagittal section through the specimen at the site of the tumour Note how the tumour surrounds and destroys the upper portion of the epiglottic cartilage. E = epiglottis; H = hyoid bone; T = thyroid cartilage

radiotherapy followed by elective laryngectomy or laryngopharyngectomy Most of these patients received 5 500 rads of Cobalt 60 followed by surgery six weeks later A much smaller number of patients received 500–2 000 rads, followed by surgery within 24–48 hours. This clinical study showed that in patients (treated from 1961 to 1966) with advanced laryngeal carcinoma, the combined method of treatment did not conclusively give a better five year survival than salvage surgery for irradiation failure or primary surgery (Bryce & Rider 1971) However other authors report more positive results with this mode of therapy (Goldman et al. 1964–1972 Constable et al 1972) From this study we received laryngectomy specimens from 43 patients with laryngeal carcinoma. Thirty four of these specimens are from patients who had a full course of radiotherapy followed by surgery six weeks later Of these 34 23 were primary tumours of the glottic region (Figs. 27 29) 10 were primary tumours of the supraglottic region (Fig 28) and 1 was a primary tumour of the subglottic region All 34 patients in this group had a total laryngectomy In 33 this was the primary mode of surgical therapy However one patient (Table III) a 51 year-old man had a horizontal supraglottic laryngectomy after a course of 5 500 rads of Cobalt 60 for an epiglottic carcinoma Eleven months later he had a total laryngectomy because he could not swallow There was no residual or recurrent tumour in the total laryngectomy specimen

The remaining 9 patients in the group had 500–2 000 rads followed by surgery mainly within 24–48 hours later Six had primary glottic tumours (Figs. 4 9) 1 had a primary supraglottic tumour and 2 had multiregional tumours.

Of the 43 patients treated by elective surgery after radiotherapy 28 had a neck dissection Ten of these had positive nodes.

Fig. 13. Epiglottic tumour with invasion of the pre-epiglottic space. Primary horizontal supraglottic partial laryngectomy *for an epiglottic-aryepiglottic fold* tumour.

( ) Sagittal section through the specimen showing how the tumour occupies the posterior (laryngeal) surface of the epiglottis, but penetrates through the dehiscences (fenestrations) in the cartilage and in the lower portion slightly invades the pre-epiglottic space. E = epiglottis, H = hyoid bone.

(b) Enlarged view of rectangle outlined in Fig. 13. Note how the tumour penetrates the dehiscences (fenestrations) of the epiglottic cartilage without destruction of the cartilage.

Autopsy cases

Three specimens were obtained at autopsy.

One patient received irradiation for a glottic carcinoma six years before his death. He was lost to follow-up until two years before his death, when he appeared with a huge recurrent bilateral inoperable tumour. He received further radiotherapy but died two years later with massive residual laryngeal tumour and multiple cervical nodal metastasis.

Another patient received radiotherapy one year before he died, for an epiglottic tumour without palpable lymph nodes. Metastatic tumour was present in multiple lymph nodes from a neck dissection performed nine months later. He developed metastasis in the opposite side of the neck and died of his disease three months later. At autopsy there was extensive tumour in the neck but no residual tumour at the primary site.

The third autopsy case had a primary glottic tumour with subglottic extension. Combined therapy was planned for this patient, but during his radiotherapy he developed thrombosis of his right carotid artery and died of cerebral infarction. Acute radiation effect was present in the tumour of his larynx (Fig. 30).

Spread of laryngeal carcinoma

The growth and spread of laryngeal carcinoma is largely determined by the site of origin of the primary tumour. The major factors in determining the direction and extent of tumour growth are the anatomic barriers produced by the laryngeal compartments so well

Fig 12 Tumour of the tip of the epiglottis Five years prior to the present surgery this patient received radiotherapy (5 500 rads Cobalt 60) for a left vocal cord carcinoma. He developed a new primary at the tip of the epiglottis treated by horizontal supraglottic partial laryngectomy

(*a*) Specimen viewed from the laryngeal surface showing the ulcerated tumour at the tip of the epiglottis.

(*b*) Sagittal section through the specimen at the site of the tumour Note how the tumour surrounds and destroys the upper portion of the epiglottic cartilage E = epiglottis; H = hyoid bone T = thyroid cartilage.

radiotherapy followed by elective laryngectomy or laryngopharyngectomy Most of these patients received 5 500 rads of Cobalt 60 followed by surgery six weeks later A much smaller number of patients received 500–2 000 rads, followed by surgery within 24–48 hours This clinical study showed that in patients (treated from 1961 to 1966) with advanced laryngeal carcinoma the combined method of treatment did not conclusively give a better five year survival than salvage surgery for irradiation failure or primary surgery (Bryce & Rider 1971) However other authors report more positive results with this mode of therapy (Goldman et al. 1964–1972 Constable et al 1972) From this study we received laryngectomy specimens from 43 patients with laryngeal carcinoma. Thirty four of these specimens are from patients who had a full course of radiotherapy followed by surgery six weeks later Of these 34 23 were primary tumours of the glottic region (Figs. 27 29) 10 were primary tumours of the supraglottic region (Fig 28) and 1 was a primary tumour of the subglottic region All 34 patients in this group had a total laryngectomy In 33 this was the primary mode of surgical therapy However one patient (Table III) a 51 year-old man had a horizontal supraglottic laryngectomy after a course of 5 500 rads of Cobalt 60 for an epiglottic carcinoma. Eleven months later he had a total laryngectomy because he could not swallow There was no residual or recurrent tumour in the total laryngectomy specimen

The remaining 9 patients in the group had 500–2 000 rads followed by surgery mainly within 24–48 hours later Six had primary glottic tumours (Figs. 4 9) 1 had a primary supraglottic tumour and 2 had multiregional tumours.

Of the 43 patients treated by elective surgery after radiotherapy 28 had a neck dissection Ten of these had positive nodes.

in Tables IV–XI. Patterns of spread in each of the laryngeal regions will be discussed separately.

Glottic carcinoma

Most of the tumours which arise in the glottic region originate on the free margins of the vocal cords. In this study the inferior boundaries of the glottic region is the conus elasticus, and the superior boundary is the lateral angle of the laryngeal ventricle (Fig. 2). Following the U I C C system we have included the anterior and posterior commissures in the glottic region.

Of the 73 tumours of glottic origin, 13 were confined to the glottic region (see Table II, Figs. 2 and 3), 55 extended into the subglottic region—24 of these spread to the subglottic region alone (Figs. 2 and 4), while the remaining 31 spread to both the subglottic and supraglottic regions (Figs. 2, 7–11, 29). An additional 5 tumours of glottic origin spread to the supraglottic region alone (Figs. 2 and 27), making a total of 36 cases with supraglottic spread.

In 35 of these 73 glottic tumours, spread had occurred to the opposite hemilarynx. In the 13 cases, where the tumour was confined to the glottic region, it crossed the anterior commissure to involve the opposite vocal cord in only one case. Similarly, in only 1 of the 5 tumours with supraglottic extension alone did the tumour cross the anterior commissure to the opposite vocal cord. Of the 24 tumours with subglottic extension, 10 had crossed the anterior commissure an 1 had crossed the posterior commissure to involve the opposite vocal cord. Of the 31 cases with subglottic and supraglottic extension, 21 had crossed the anterior midline to the opposite hemilarynx—19 of these were at the anterior commissure (glottic) level, and 2 had crossed anteriorly at the false vocal cord level only. Five tumours had crossed the posterior commissure to the opposite hemilarynx—4 of these had crossed both the anterior and posterior commissures.

Invasion of one or more of the intrinsic laryngeal muscles was common and was observed in 57 out of 73 tumours in this group.

in Tables IV–XI. Patterns of spread in each of the laryngeal regions will be discussed separately.

Glottic carcinoma

Most of the tumours which arise in the glottic region originate on the free margins of the vocal cords. In this study the inferior boundaries of the glottic region is the conus elasticus, and the superior boundary is the lateral angle of the laryngeal ventricle (Fig. 2). Following the U.I.C.C. system we have included the anterior and posterior commissures in the glottic region.

Of the 73 tumours of glottic origin, 13 were confined to the glottic region (see Table II, Figs. 2 and 3). 55 extended into the subglottic region—24 of these spread to the subglottic region alone (Figs. 2 and 4), while the remaining 31 spread to both the subglottic and supraglottic regions (Figs. 2, 7–11, 29). An additional 5 tumours of glottic origin spread to the supraglottic region alone (Figs. 2 and 27), making a total of 36 cases with supraglottic spread.

In 35 of these 73 glottic tumours, spread had occurred to the opposite hemilarynx. In the 13 cases, where the tumour was confined to the glottic region, it crossed the anterior commissure to involve the opposite vocal cord in only one case. Similarly, in only 1 of the 5 tumours with supraglottic extension alone did the tumour cross the anterior commissure to the opposite vocal cord. Of the 24 tumours with subglottic extension, 10 had crossed the anterior commissure and 1 had crossed the posterior commissure to involve the opposite vocal cord. Of the 31 cases with subglottic and supraglottic extension, 21 had crossed the anterior midline to the opposite hemilarynx—19 of these were at the anterior commissure (glottic) level, and 2 had crossed anteriorly at the false vocal cord level only. Five tumours had crossed the posterior commissure to the opposite hemilarynx—4 of these had crossed both the anterior and posterior commissures.

Invasion of one or more of the intrinsic laryngeal muscles was common and was observed in 57 out of 73 tumours in this group.

described by Pressman (1956) Pressman et al. (1960) and Tucker & Smith (1962) Submucosal tumour spread is a feature common to all laryngeal and hypopharyngeal carcinomas. *It is the most common method by* which laryngeal tumours cross from one side of the larynx to the other and also the route by which tumours cross the laryngeal ventricle. Tumours spreading along the length of the vocal cord do so within Reinke's space As noted earlier *the cartilaginous framework of* the larynx provides an anatomic barrier to the spread of tumours This framework however *has points of weakness, which the tumours* seek out These points of weakness will be amplified when dealing with tumours arising in a *specific region Structures invaded by the* laryngeal tumours in our series are detailed

In addition to these 9 cases with positive cervical nodes, 5 more had metastatic tumour in the prelaryngeal (Delphian) node/s/ (Fig. 21 *a*), making a total of 14 with positive nodes at the time of laryngectomy (Table XII).

Comment. Vertical extension of tumours arising from the glottic region into the subglottic or supraglottic regions occurred more frequently than horizontal extension to the opposite hemilarynx, an observation also made by Pressman et al. (1960).

However the conus elasticus resisted tumour invasion for a long time and could in some cases be seen bulging downwards. Meurman (1936) noted that elastic fibers were very resistant to "the pathologic influence of the tumour".

Glottic tumours which spread outside the laryngeal framework do so most commonly through the cricothyroid membrane or cartilage at the anterior commissure (Figs. 5, 6, 21 *b*). This would appear to be related to the ease with which these tumours spread along the vocal cord within Reinke's space, and also to the close proximity of the mucosa to the thyroid ala at the anterior commissure with no intervening muscle. Ridpath (1930) first described the fibrous cord in the anterior midline that Broyles (1943) called the "anterior commissure tendon". This tendon blends with the underlying cartilage without coverage of perichondrium. Glottic tumours, when they reach the anterior commissure, very rapidly extend subglottically to penetrate the cricothyroid membrane and escape outside the laryngeal framework (Fig. 6) (Ogura, 1955, Shaw 1965, Willis, 1967, Olofsson et al. 1972). In our series, 22 of the 27 cases with spread outside the larynx used this pathway of exit. Nassar and Bridger (1971) and Bridger and Nassar (1971, 1972) have suggested that the submucosal glandular structures in this region make a significant contribution to this method of spread.

Glottic tumours that invade the thyroid cartilage tend to do so at the anterior commissure (McKenty 1926, Broyles, 1943, Ogura, 1955)—a feature also explained by the close proximity of the cartilage to the vocal cord with no intervening muscle. In our series the thyroid cartilage was invaded in 26 cases, and in 21 of these the invasion occurred at the anterior commissure. In 17 of these the tumour penetrated the thyroid cartilage to extend outside the larynx (Figs. 5, 21 *b*). (As would be expected, the larger and more extensive tumours with both supraglottic and subglottic extension included all 17 of these cases.) In addition to invading the thyroid cartilage, many of these tumours also had penetrated the cricothyroid space laterally (Figs. 9, 29).

Several other authors have drawn attention to these same features by referring to these large tumours, which traverse the ventricle, as "transglottic" (McGavran et al., 1961, Kirchner 1969). Baclesse (1949) also noted that tumours which surrounded the ventricle invaded the cartilage early and suggested that proximity of the tumours to the thyroid ala could explain this observation. The spread within the paraglottic space is perhaps another important factor (Pressman et al., 1960, Tucker & Smith, 1962).

When invasion of the laryngeal framework occurs, it is the ossified portions of the framework which receive the brunt of the attack (Szlęzak, 1966, Kirchner 1969, Norris et al. 1970). Ogura (1955) also noted that tumour well within the cartilage spread in all directions until the external perichondrium was invaded. Similar findings were present in our series (Figs. 5, 9, 11, 29). Occasionally in the very large tumours, we noted islands of residual cartilage surrounded by tumour.

Supraglottic carcinoma

The supraglottic region is bounded inferiorly by the vocal cords (Fig. 2), and superiorly by the free margin of the epiglottis and the aryepiglottic folds (following the U.I.C.C. system).

Twenty-five tumours in this series arose in the supraglottic region—15 on the dorsal surface of the epiglottis and the remaining 10 on

As one would expect most of the 16 tumours where no muscle invasion was observed were small superficial lesions confined to the vocal cord The muscle most frequently invaded was the thyroarytenoid (Table XI)

In 46 of the 73 glottic carcinomas, the tumour remained confined to the larynx. Twenty-one of these had invaded one or more of the laryngeal cartilages (Table IV) None of the smaller tumours which were confined to the glottic region invaded cartilage (Fig 3) The arytenoid cartilage was the most frequently invaded (15 cases) The thyroid ala was invaded by 4 tumours and in 3 of these invasion occurred at the anterior commissure region

In 27 cases (the remainder of the total group of 73) the tumour had spread beyond the larynx. The spread outside the laryngeal framework was either through the thyroid ala (Figs. 5 9 29) or through the cricothyroid membrane anteriorly (Figs. 5 6 21 *b*) and/or through the cricothyroid space (spaces) laterally (Figs. 9 10 29) (Table V) In 25 of the 27 the tumour involved one or more of the laryngeal cartilages in only 2 did it penetrate through the cricothyroid membrane without involving the cartilages. The most common site of invasion with penetration and breakthrough of the cartilage was the thyroid cartilage near the anterior commissure (Fig. 5) However in only 2 of the 27 cases with extension outside the larynx was the sole mode of exit through this cartilage In an additional 15 cases, penetration of the thyroid ala was combined with extension through the cricothyroid membrane or space If a glottic carcinoma involves the anterior commissure and extends subglottically it is close to the cricothyroid membrane and escapes by this route early and often (Fig 6) It did so in 22 of our cases. This particular escape route unaccompanied by lateral extension through the cricothyroid space was seen in all 7 of the cases with vertical distribution confined to the glottic and subglottic regions (Fig. 5) In contrast of the 20 larger tumours involving glottic supraglottic and subglottic regions 15 had escaped through the cricothyroid membrane anteriorly but of these 11 had also extended laterally through the cricothyroid space—four of them bilaterally This group of 20 tumours included 9 that other authors (McGavran et al. 1961 Kirchner 1969) would have classed as transglottic tumours (Figs. 10 29)

Several of the very extensive tumours used more than one portal of exit. Four tumours had large subglottic extension and involvement of the upper trachea, as well as lateral spread through the cricothyroid space Four tumours invaded the thyroid gland by direct extension and another had metastasized to the thyroid gland. Two of the tumours had extended into the pre-epiglottic space and both of these involved the base of the epiglottis (Table X)

Vascular invasion was less frequent than we expected and was noted in only 19 cases. McGavran et al. (1961) reported a similar figure No vascular invasion was noted in any of the 13 tumours confined to the glottic region All 19 instances occurred in the 55 glottic tumours with subglottic extension. Most of the invaded vessels were immediately beneath the conus elasticus near its base Eighteen of these 19 cases also had cartilage invasion.

Perineural invasion was observed in 12 cases and was usually noted in the connective tissue deep to the thyroarytenoid muscle near the lower end of the thyroid ala (branches of the recurrent laryngeal nerve) Perineural invasion could sometimes be observed many mm from the main tumour mass. All but three of these cases also had vascular invasion

Of the total 73 cases, 29 had a neck dissection performed at the time of laryngectomy (one patient had bilateral neck dissection—both with metastasis to the lymph nodes) Fourteen of these dissections were performed in the group of 46 cases where the tumour was confined to the larynx—three of these had metastatic carcinoma in cervical nodes. Fifteen of the dissections were performed in the group of 27 cases where the tumour had spread outside the larynx—six had metastatic carcinoma in cervical nodes (Table XII)

In addition to these 9 cases with positive cervical nodes, 5 more had metastatic tumour in the prelaryngeal (Delphian) node/s/ (Fig. 21 *a*), making a total of 14 with positive nodes at the time of laryngectomy (Table XII).

Comment Vertical extension of tumours arising from the glottic region into the subglottic or supraglottic regions occurred more frequently than horizontal extension to the opposite hemilarynx, an observation also made by Pressman et al. (1960).

However the conus elasticus resisted tumour invasion for a long time and could in some cases be seen bulging downwards. Meurman (1936) noted that elastic fibers were very resistant to "the pathologic influence of the tumour"

Glottic tumours which spread outside the laryngeal framework do so most commonly through the cricothyroid membrane or cartilage at the anterior commissure (Figs. 5 6, 21 *b*). This would appear to be related to the ease with which these tumours spread along the vocal cord within Reinke s space, and also to the close proximity of the mucosa to the thyroid ala at the anterior commissure with no intervening muscle Ridpath (1930) first described the fibrous cord in the anterior midline that Broyles (1943) called the "anterior commissure tendon" This tendon blends with the underlying cartilage without coverage of perichondrium Glottic tumours, when they reach the anterior commissure, very rapidly extend subglottically to penetrate the cricothyroid membrane and escape outside the laryngeal framework (Fig. 6) (Ogura, 1955 Shaw 1965 Willis, 1967 Olofsson et al 1972). In our series, 22 of the 27 cases with spread outside the larynx used this pathway of exit Nassar and Bridger (1971) and Bridger and Nassar (1971 1972) have suggested that the submucosal glandular structures in this region make a significant contribution to this method of spread

Glottic tumours that invade the thyroid cartilage tend to do so at the anterior commissure (McKenty 1926 Broyles, 1943 Ogura, 1955)—a feature also explained by the close proximity of the cartilage to the vocal cord with no intervening muscle. In our series, the thyroid cartilage was invaded in 26 cases, and in 21 of these the invasion occurred at the anterior commissure. In 17 of these the tumour penetrated the thyroid cartilage to extend outside the larynx (Figs. 5 21 *b*). (As would be expected, the larger and more extensive tumours with both supraglottic and subglottic extension included all 17 of these cases.) In addition to invading the thyroid cartilage, many of these tumours also had penetrated the cricothyroid space laterally (Figs. 9 29)

Several other authors have drawn attention to these same features by referring to these large tumours, which traverse the ventricle as "transglottic" (McGavran et al., 1961 Kirchner 1969) Baclesse (1949) also noted that tumours which surrounded the ventricle invaded the cartilage early and suggested that proximity of the tumours to the thyroid ala could explain this observation The spread within the paraglottic space is perhaps another important factor (Pressman et al. 1960 Tucker & Smith, 1962).

When invasion of the laryngeal framework occurs, it is the ossified portions of the framework which receive the brunt of the attack (Szlęzak, 1966 Kirchner 1969 Norris et al. 1970). Ogura (1955) also noted that tumour well within the cartilage spread in all directions until the external perichondrium was invaded Similar findings were present in our series (Figs. 5, 9 11 29). Occasionally in the very large tumours, we noted islands of residual cartilage surrounded by tumour

Supraglottic carcinoma

The supraglottic region is bounded inferiorly by the vocal cords (Fig. 2), and superiorly by the free margin of the epiglottis and the aryepiglottic folds (following the U I.C.C. system).

Twenty-five tumours in this series arose in the supraglottic region—15 on the dorsal surface of the epiglottis and the remaining 10 on

Fig 15 Supraglottic tumour with extension to the glottic region. This patient had a huge supraglottic tumour treated by primary laryngectomy and right neck dissection. Metastatic carcinoma was present in the cervical lymph nodes, and was also present in the left neck dissection subsequently performed

(*a*) Gross photograph of the laryngectomy specimen viewed from the posterior aspect with the cricoid opened in the midline. There is a large fungating tumour mass occupying the base of the epiglottis, the *right aryepiglottic fold the right false vocal cord* and overhanging the vocal cords.

Fig. 17. Subglottic circumferential tumour. Coronal section through a total laryngectomy specimen close to the anterior commissure. The tumour (as outlined by arrows) does not involve the free margins of the vocal cords, but penetrates the conus elasticus into the left vocal cord. This primary subglottic tumour had a circumferential distribution within the subglottic region. This patient had a total laryngectomy 5½ months following a full course of radiotherapy (5 500 rads Cobalt 60). C = cricoid cartilage; E = epiglottis; T = thyroid ala.

tion—one side contained positive nodes (Table XII).

Vascular invasion was noted in only one of our supraglottic cases and perineural invasion of the superior laryngeal nerve was noted in 3 cases.

Comment. Supraglottic tumours which spread beyond the supraglottic region tend to spread either upwards and outwards, or downwards—seldom in both directions. These tumours tend to have "pushing" margins (Fig. 15). As indicated earlier in this study nearly one quarter of the supraglottic tumours extended into the glottic region (Figs. 14, 15) contrary to the experience of other authors.

Coutard & Valat (1927), Leroux Robert (1936) and Baclesse (1949) and later Bocca et al. (1968) noted that supraglottic tumours do

not involve the glottic region. However they often cross the anterior midline and extend bilaterally above the vocal cords (Coutard & Valat 1927). McGavran et al. (1961) made a distinction between tumours having an "infiltrative margin" and those with "pushing margins". They found the latter more common among supraglottic carcinomas. Bocca et al. (1968) emphasized that "the larynx consists of two distinct parts, an upper and a lower part, whose line of demarcation runs at the level of the vocal cord" and stressed the different

embryologic derivations and different lymphatic supplies. Kirchner & Som (1971) found that exophytic lesions of the supraglottic larynx are the kind that tend to remain confined above the ventricle and the anterior commissure and that these do not invade the thyroid ala. They indicated, however that ulcerative lesions from the supraglottic region may extend downward across the anterior commissure and, when they do so frequently invade and destroy the anterior portion of the laryngeal framework. Hence these authors refer to tumours with this type of infiltrative growth as "transglottic". They make the important observation that microscopic invasion of the thyroid cartilage does not occur unless, at the time of surgery the inferior edge of the growth is visible below the level of the anterior commissure. In our series of 25 tumours, only two invaded the thyroid cartilage and, in one of these, the tumour did extend below the anterior commissure.

Despite these reports, Szlezak (1966) found 10 cases in his series of 25 supraglottic tumours that extended down to or below the glottic region. In our series 24% (6 out of 25) also behaved in this manner. It should be noted, however that both of these latter series deal with highly selected supraglottic tumours with an emphasis on large and/or recurrent neoplasms.

The pre-epiglottic space invasion is very common in this supraglottic group (see Table X) especially among the tumours arising on the epiglottis. Detailed analysis of the invasion of the preepiglottic space and of the nodal metastasis of supraglottic tumours is discussed later (see page 45).

Subglottic carcinoma

The subglottic region is bounded superiorly by the conus elasticus and inferiorly by the lower margin of the cricoid cartilage (Fig. 2). All four tumours that arose in the subglottic region had spread through the conus elasticus to the glottic region, but none of them involved the mucosa of the free margin of the vocal cords (Figs. 16, 17).

Three of the 4 tumours involved both hemilarynges and 2 of these crossed both the anterior and posterior midline. The intrinsic laryngeal muscles were invaded in all four (see Table XI). All four of these tumours had invaded the thyroarytenoid muscle. One had also penetrated the cricotracheal space to involve the posterior cricoarytenoid muscle. The laryngeal cartilages were invaded in 3 of the 4 cases (see Table VIII); the cricoid and thyroid cartilages each were invaded twice and the arytenoid cartilage once.

The tumours extended beyond the larynx in 3 of the 4 cases. In 2 the tumour had

[b] *5 of these had neck dissections. 2 of these 5 contained metastatic carcinoma.*

extended anteriorly through the cricothyroid membrane and appeared outside the larynx. In one the tumour invaded the upper trachea and extended into the hypopharyngeal submucosa (*vide supra*)

Vascular invasion was observed in 3 cases and perineural invasion in 2. Combined neck dissections were performed in two of the 4 cases—one had positive nodes (Table XII)

Comment The anatomic boundaries of the subglottic region have always been poorly defined Neither the U I C C nor the A J C include tumours arising from the undersurface of the vocal cord as subglottic primaries. *Histologically the only structure in this region* that acts as a barrier is the conus elasticus. In keeping with St Clair Thomson (1937) Müller (1955) and Lederman (*1970 1971*) we consider the undersurface of the vocal cord (below the conus elasticus) as part of the subglottic region

St Clair Thomson (1937) noted the tendency of subglottic tumours to spread circumferentially without involving the anterior commissure This tendency was also prominent in our material and occurred in three out of four cases.

Clerf (1940) observed that subglottic lesions often were extensive before laryngeal symptoms occurred.

Baclesse (1949) described the subglottic tumours as flat and irregular with submucosal spread and with ill-defined outlines in contrast to the proliferative supraglottic tumours. Ogura (1955) found most of them "ulcero-fungating Our four cases possess these characteristics and three of them extended down to the lower border of the cricoid cartilage

Ogura (1955) and Kirchner (1969) noted that subglottic tumours frequently invaded cartilage and also that they tended to spread through the cricothyroid membrane Three of our four cases invaded cartilage and two had extended through the cricothyroid membrane

Harrison (1971) stressed the undetectable spread of subglottic carcinoma to the hypopharynx This type of spread occurred in one of our patients.

Multiregional carcinoma

All 8 tumours in this group involved all three laryngeal regions. All eight involved both hemilarynges—*eight crossed the anterior mid* line and three af these also crossed the posterior midline

All 8 tumours invaded many of the *intrinsic* laryngeal muscle groups, and all eight invaded one or more laryngeal cartilages (see Table IX)

The tumour extended beyond the larynx in all eight tumours in this group it penetrated the cricothyroid membrane in all eight the cricothyroid space in seven and the thyroid ala in seven cases (Figs 18 19 20) The tumour had extended into the thyroid gland in three and into the pre-epiglottic space in five (*vide infra*)

Vascular invasion was present in four cases and perineural invasion in three cases.

Five of the eight tumours had spread to the

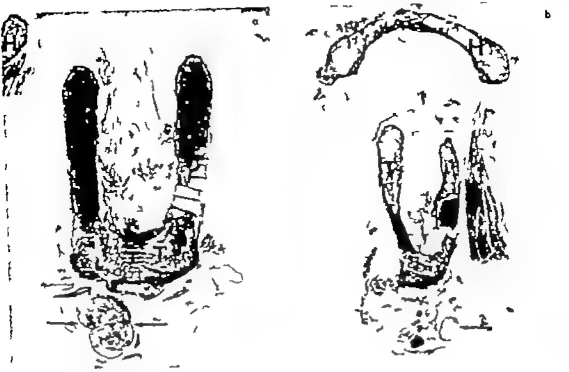

Fig 21 The prelaryngeal (Delphian) lymph node

lymph nodes at the time of laryngectomy In one a single cervical node was sampled and contained metastatic tumour In another the prelaryngeal (Delphian) lymph node in the laryngectomy specimen contained metastatic tumour Five patients had combined neck dissection—three had positive nodes (Table XII).

Comment As one might expect, these very large tumours invade extensively the adjacent structures, spread outside the larynx through multiple exit portals, and frequently have metastasized to lymph nodes at the time of laryngectomy

Pre-epiglottic space invasion

The pre-epiglottic space is that laryngeal compartment bounded posteriorly by the epiglottic cartilage, anteriorly by the thyrohyoid membrane and the hyoid bone, and superiorly by the hyoepiglottic ligament. The lateral parts are in direct continuity with the paraglottic space (Tucker & Smith, 1962).

The body of the epiglottic cartilage is fenestrated and tumours arising on the dorsal aspect of the epiglottis often reach the pre epiglottic space by travelling through these fenestration (dehiscences) either with or without destruction of the cartilage (Figs. 13 15) Ten of the 15 tumours arising on the epiglottis invaded the pre-epiglottic space either via these fenestrations (Fig. 13) or by destroying the intervening epiglottic cartilage (Fig. 15) (see Table X). One additional supraglottic tumour invaded the pre-epiglottic space from the lateral aspect, without invasion of the epiglottic

Table XII *Metastasis to lymph nodes (laryngeal carcinoma)*

Carcinomas (110)	Neck dissections (50)	Neck dissections with metastasis to lymph nodes (23)	Metastasis to prelaryngeal lymph nodes (Delphian) (8)

lymph nodes at the time of laryngectomy In one a single cervical node was sampled and contained metastatic tumour In another the prelaryngeal (Delphian) lymph node in the laryngectomy specimen contained metastatic tumour Five patients had combined neck dissection—three had positive nodes (Table XII).

Comment As one might expect, these very large tumours invade extensively the adjacent structures, spread outside the larynx through multiple exit portals, and frequently have metastasized to lymph nodes at the time of laryngectomy

Pre-epiglottic space invasion

The pre-epiglottic space is that laryngeal compartment bounded posteriorly by the epiglottic cartilage, anteriorly by the thyrohyoid membrane and the hyoid bone, and superiorly by the hyoepiglottic ligament. The lateral parts are in direct continuity with the paraglottic space (Tucker & Smith, 1962).

The body of the epiglottic cartilage is fenestrated and tumours arising on the dorsal aspect of the epiglottis often reach the pre epiglottic space by travelling through these fenestration (dehiscenses) either with or without destruction of the cartilage (Figs. 13 15). *Ten of the 15* tumours arising on the epiglottis invaded the pre-epiglottic space either via these fenestrations (Fig. 13) or by destroying the intervening epiglottic cartilage (Fig 15) (see Table XI. One additional supraglottic tumour invaded the pre-epiglottic space from the lateral aspect, without invasion of the epiglottic

cartilage. Two tumours originating in the glottic region involved the base of the epiglottis with extension into the pre-epiglottic space. Five multiregional tumours also invaded the pre-epiglottic space—four of these involved the dorsal surface of the epiglottis, and the fifth involved the false vocal cord and the aryepiglottic fold

Comment The pre-epiglottic space has been given a number of names in the past among which "space of Boyer is probably the most popular Norris et al. (1970) indicate that Boyer apparently described the prelaryngeal bursa anterior to the thyrohyoid membrane and not the space that we know as pre-epiglottic space

Clerf (1944) stated that the pre-epiglottic space was filled with cellular adipose tissue and contained no lymph nodes but was traversed by numerous lymphatic channels. Dayal et al. (1972) studied this space using dye injections and by dissolving the adipose tissue They could not identify lymph nodes in any of their studies, nor have we been able to identify any lymphoid tissue within the space in any of our serially sectioned specimens.

Of the total 110 laryngeal carcinomas 18 had invaded the pre-epiglottic space All but one of these 18 tumours also involved the dorsal surface of the epiglottis and would therefore be visible to the examining clinician As would be expected, invasion of the pre-epiglottic space was most frequent in the supraglottic tumours, especially those arising on the epiglottis. The pre-epiglottic space was invaded in nearly 70% of our epiglottic tumours and in more than 40% of all supraglottic tumours. These figures are similar to those published by other authors (Ogura, 1955 Szlęzak, 1966 Bocca et al 1968 Kirchner 1969 Norris et al 1970) Whereas it would appear that tumours occupying the anterior commissure could easily spread to the pre epiglottic space such a finding was observed in only two cases in our series

It is necessary to stress that at operation the whole pre-epiglottic space (PES) should be removed in supraglottic carcinomas and in all tumours occupying the dorsal (laryngeal) surface of the epiglottis.

Vocal cord fixation in laryngeal carcinoma

Impaired mobility or fixation of the vocal cords is an important clinical sign in assessing laryngeal tumours. This clinical finding was reported in 39 of the 110 tumours in our series, and was probably present in at least 6 additional cases in the multiregional group As is indicated in Table XI invasion of the thyroarytenoid muscle was present in all 39 cases (Fig 4 9 11 16 20 29). Invasion of other intrinsic muscle groups (Figs. 9 11 20 29) perineural invasion (Fig 20) and invasion of the cricoarytenoid joint (Fig. 11) were less frequently observed, and were thought to be of lesser importance as etiologic factors. In those cases where only vocal cord mobility was impaired there was a lesser degree of invasion (Fig 17). Fixation of the vocal cord indicated invasion of the deeper laryngeal structures—20 tumours invaded or penetrated the thyroid ala and 23 extended outside the laryngeal framework (Figs. 9 11 20 29) Vocal cord fixation as one would expect, occurs most frequently in primary glottic carcinoma. The histopathologic findings in glottic carcinoma with vocal cord fixation have been discussed in detail in an additional paper (Olofsson et al 1973)

Invasion of the thyroid gland

Ogura (1955) noted thyroid gland invasion in 10% of his carcinomas—6 out of 59 (this series included "extrinsic carcinoma" arising in the piriform sinus) Szlęzak (1966) noted thyroid gland invasion in 3 out of 57 cases. Other authors have also reported thyroid gland involvement (Gammarrota 1965) Harrison (1971) advocated removal of the isthmus of the thyroid gland and one or both lobes of the thyroid when dealing with subglottic carcinomas.

There was direct invasion of the thyroid gland in 7 of our cases. In 3 of these, the tumour was classified as "multiregional" and in the remaining four as "glottic" with both supra- and subglottic extension. Metastatic spread to the thyroid gland via either lymphatic or hematogenous route occurred in an eighth case where there was a separate focus of tumour in the lower lobe of the thyroid gland. This tumour, a large glottic lesion with subglottic extension, had invaded the thyroid ala and spread through the cricothyroid membrane.

Metastasis to lymph nodes (Table XII)

Prophylactic neck dissection is not commonly employed in the treatment of laryngeal tumours in Toronto—this procedure is mainly reserved for patients with palpably enlarged cervical nodes. It is performed more frequently in supraglottic tumours and in larger glottic tumours. In our series neck dissections were performed at the time of laryngectomy in 50 out of the 110 laryngeal carcinomas. Twenty-nine were done in the glottic tumours (29 out of 73), 14 in the supraglottic primaries (14 out of 25), 2 in the subglottic group (2 out of 4) and 5 in the multiregional group (5 out of 8). As might be expected, neck dissection was done more commonly in the patients with very large glottic tumours and was actually carried out in 15 out of the 27 glottic tumours with extension outside the laryngeal framework. The incidence of positive cervical nodes was highest in the supraglottic group where 9 out of 14 neck dissections contained metastatic carcinoma. In contrast, only 9 out of 29 neck dissections in the glottic group contained positive nodes, but, in this group we found 5 additional prelaryngeal (Delphian) nodes.

Ogura & Bello (1952) advocated combined laryngectomy and radical neck dissection for advanced carcinoma with or without palpable nodes. In a series of 75 supraglottic carcinomas, in which neck dissection was performed in all patients, Som (1970) found 24 instances of metastasis to cervical nodes—12 were in palpable lymph nodes and 12 in nodes that were not clinically enlarged. Because of the high incidence of clinically undetectable positive nodes, he advocated prophylactic neck dissection in all supraglottic tumours, and so did Surala & Lauerma (1967).

McGavran et al. (1961) in a study of 96 patients with laryngeal tumours, all of whom had neck dissections at the time of laryngectomy, found metastatic tumour in cervical nodes in 52% of transglottic tumours, 33% of supraglottic tumours, and 19% of the infraglottic tumours. Ogura (1955) in a study of 43 patients with laryngeal carcinomas, all of whom had neck dissections at the time of laryngectomy reported 50% (9 out of 18) with positive cervical nodes in the endolaryngeal tumours (arising in vocal cord, ventricle and false vocal cord), and 54% (7 out of 13) in the subglottic tumours, and 58% (7 out of 12) in the supraglottic tumours. The high incidence of positive paratracheal lymph nodes in tumours involving the subglottic area was stressed by Harrison (1971).

Ogura (1955) noted a higher frequency of nodal involvement when the thyroid cartilage was invaded by tumour. Invasion of the thyroid ala is more frequently seen in tumours of glottic origin—it was present in 26 of the 73 glottic tumours in our series. Of these 26, 16 had neck dissection at the time of laryngectomy—7 had positive cervical nodes. An additional 3 had a positive prelaryngeal (Delphian) node. Of the remaining 47 patients with glottic carcinoma, only 13 had neck dissection and, in only 2 did the nodes contain metastatic tumour, though an additional two had positive prelaryngeal (Delphian) nodes (Table XIII).

In the whole series of 110 laryngeal tumours, 38 invaded the thyroid cartilage and, of these 25 had neck dissection—12 had positive cervical nodes, and 4 others had positive prelaryngeal nodes, making a total of 16 out of 38 with positive nodes. In contrast, in those 72 patients with tumours without invasion of the thyroid ala, only 12 had positive

Table XIII *Thyroid cartilage invasion — lymph node metastasis (primary glottic carcinoma (73))*

		Neck dissections performed	Neck dissections with metastasis to lymph nodes
Invasion of the thyroid cartilage	26	15	7 (+ 3)[a]
No invasion of the thyroid cartilage	47	13	3 (+ 2)[a]

[a] Additional pos prelaryngeal (Delphian) lymph nodes.

nodes. In 10 of these positive cervical nodes were found in the neck dissection specimens and two other had positive prelaryngeal (Delphian) nodes It should be noted however that in the latter group of 72 cases neck dissections were performed at the time of laryngectomy in only 25

As one would expect, we found a higher *incidence of nodal metastasis in the glottic* carcinomas that had extended outside the laryngeal framework at the time of laryngectomy Of the 27 patients in this group 6 of the 15 neck dissections had positive cervical lymph nodes and 3 more had positive prelaryngeal (Delphian) nodes—a total of 9 out of 27 with positive lymph nodes. In contrast of the 46 patients with tumours confined to the larynx 14 had neck dissections—3 with positive nodes. Two more had positive prelaryngeal lymph nodes, making a total of 5 *out of 46 with nodal metastasis.*

The term Delphian node/s/ was introduced by Cope (1963) dealing with thyroid carcinoma. There is always a lymph node or more to be found just above the thyroid isthmus anterior to the lower portion of the thyroid cartilage This node or group of nodes will be exposed first at surgery and if diseased it will foretell the nature of the disease process to be found in the thyroid gland In only 8 cases in the entire series did the prelaryngeal or Delphian node/s/ contain metastatic tumour (Table XII) All of these tumours involved the subglottic region and in 6 the tumour had spread through the cricothyroid membrane and outside of the laryngeal framework. *In these 6* tumour was found immediately adjacent to the lymph node as well as within the lymph node these nodes could have been involved by *direct extension rather than by lymphatic* spread in some cases. In only two was the primary tumour confined to the larynx In these nodal metastasis was due to spread via lymphatic channels (Fig 21 *a*) In many other cases with large tumours involving the anterior part of the larynx and spread through the cricothyroid membrane we were surprised to see extensive growth adjacent to the prelaryngeal lymph node without involvement of the node (Fig 21 *b*).

In five of the eight cases with positive prelaryngeal lymph nodes neck dissection was performed at the time of laryngectomy metastatic tumour was found in cervical lymph nodes in two of these Ogura (1955) suggested a correlation between positive prelaryngeal and *positive cervical lymph nodes* This was not borne out by our material

The low frequency of prelaryngeal nodal involvement found in our series correlates well with similar findings of McGavran et al. (1961) *It seems that when dealing with laryngeal carcinomas* surgeons have overemphasized the importance of the prelaryngeal lymph nodes.

Ogura (1955) noted that invasion of the *pre-epiglottic space in* epiglottic and aryepiglottic fold carcinomas was associated with a high incidence of metastasis to the cervical lymph nodes. In analysing our supraglottic primary tumours, 7 of the 11 cases with pre*epiglottic space* invasion (Figs 13 15) had

combined neck dissection—5 had positive nodes. Similarly 7 of 14 without pre-epiglottic space invasion had combined neck dissections —four had positive nodes.

Perineural invasion is associated with a higher rate of nodal metastasis (McGavran et al 1961). Perineural invasion was noted in 20 cases in our series (Figs 19 20). Ten of the 20 had neck dissections—5 had positive nodes. Positive prelaryngeal lymp nodes were found in 5 additional cases

Vascular invasion was noted in 29 cases in our series (Fig 19). Eleven of these had neck dissections—7 had positive nodes. In three more positive prelaryngeal lymph nodes were found

Comment It should be noted that the relatively low frequency of combined neck dissection in Toronto does not allow valid comparison of our figures with those from other centres where neck dissection is done on a far greater proportion of patients.

HYPOPHARYNGEAL CARCINOMA (29 CASES)

As in laryngeal carcinomas, we followed the basic U I C C criteria in the hypopharyngeal carcinomas The classification "multiregional" has been applied to those tumours in which the site of origin could not be determined due to the extreme size or extensive nature of the tumour

Histologic grading

Using Broders classification (Broders 1932) all the tumours were graded in terms of degree of differentiation (Table XIV)

None of the hypopharyngeal tumours were classified as Grade I, though one tumour with extensive *in situ* carcinoma might be so graded. Twelve tumours were classed as Grade II (this included 5 of the 7 postcricoid tumours). Fourteen were classed as Grade III and two as Grade IV

Table XIV *Histologic grading of hypopharyngeal carcinomas (Broders')*

	I	II	III	IV	Total
Piriform sinus		[illegible]	11	2	19
Postcricoid	1	5	1		7*
Multiregional		1	2		3
Total	1	12	14	2	29

* One *in situ* carcinoma

One of the hypopharyngeal tumours was unusual (Tables XIV and XV). A woman had a partial pharyngectomy for piriform sinus carcinoma when she was 42. Sixteen years later she had 5 500 rads of Cobalt 60 for *in situ* carcinoma in the postcricoid area. Four years later at age 62, she had a laryngopharyngectomy for extensive *in situ* carcinoma of the hypopharyngeal mucosa.

Two patients had radiotherapy for thyroid diseases 30 and 54 years prior to the detection of their hypopharyngeal carcinoma.

Comment A number of authors have pointed out that hypopharyngeal tumours tend to be less well differentiated than laryngeal tumours. Ogura (1955) indicated that Broders Grade III was the predominant tumour in his study of piriform sinus carcinomas. McGavran et al. (1963), in a study of 52 piriform sinus carcinomas, described 21 as being "moderately differentiated" and 31 as being "poorly differentiated" MacComb & Fletcher (1967) referred to laryngeal tumours as being "moderately well differentiated" and hypopharyngeal tumours as being "moderately undifferentiated" Ackerman & del Regato (1970) described hypopharyngeal tumours in general as being "rather undifferentiated" but did note that the lesions arising in the retrocricoid area were somewhat better differentiated.

In our own study a much higher proportion of the hypopharyngeal tumours (55%) were poorly differentiated (Grade III or Grade IV) in contrast to the laryngeal tumours where

Fig 22 Piriform sinus carcinoma This patient received a full course of radiotherapy (5 500 rads Cobalt 60) followed by a laryngopharyngectomy and *right neck dissection six weeks later Metastatic car* cinoma was present in the cervical lymh nodes.

(*a*) Gross photograph of the laryngopharyngectomy specimen showing the large indurated scarred area occupying the right piriform sinus.

(*b*) Coronal section of the laryngopharyngectomy specimen through the cricoid plate. Note the residual tumour mass (arrows) beneath the extensive *submucosal scarring in the piriform sinus region A* arytenoid cartilage· C = cricoid cartilage E epiglottis, T = thyroid cartilage

only 13% were poorly differentiated. In general the postericoid tumours in our series tended to be better differentiated tumours.

Site of origin and anatomic distribution

Of the 29 cases, 19 arose in the piriform sinus (Figs. 22 23)—14 of these were confined to the piriform sinus one had spread to the mucosa of the postcricoid region and posterior pharyngeal wall and four had extended into the larynx.

Seven of the hypopharyngeal tumours arose in the postericoid region (Fig 24)—six of these were confined to this region but one had extended to the posterior pharyngeal wall

We could identify no tumours which definitely arose in the posterior pharyngeal wall.

Three of the tumours were classified as multiregional (Figs. 25 26)—one of these probably arose in the postcricoid region (Fig. 26) and the other two probably arose in the piriform sinus (Fig 25) All three tumours involved all three regions, two of them extended into the upper esophagus (Figs. 25 26) and the third extended into the larynx.

Clinical management (see Table XV)

Although the same basic therapeutic categories used in the laryngeal tumours also apply in the hypopharyngeal carcinomas only *one of the patients received primary surgery* and only 3 patients had surgery for irradiation failure

Fig. 23. Piriform sinus carcinoma. This patient had full course of radiotherapy (5 000 rads Cobalt 60) for left piriform sinus carcinoma. Six weeks later a laryngopharyngectomy and left neck dissection was performed. Metastatic tumour was present in the cervical lymph nodes.

(*a*) Gross photograph of the left piriform sinus region of the laryngopharyngectomy specimen illustrating the mobile well circumscribed tumour mass (arrows).

(*b*) Horizontal section through the laryngopharyngectomy specimen at the level of the false vocal cords. The tumour (arrows) is well circumscribed and confined to the mucosa and submucosa of the left piriform sinus. A = arytenoid cartilage; FC = false vocal cord; IAM = interarytenoid muscle; T = thyroid cartilage.

[a] One patient had a piriform sinus carcinoma successfully treated by radiotherapy She died of postoperative complications following laryngopharyngectomy for a second primary tumour in the postcricoid area.

[b] One patient had a partial pharyngectomy for a piriform sinus carcinoma in 1950. Sixteen years later she received irradiation for carcinoma *in situ* of the hypopharynx. Four years later a laryngopharyngectomy was performed for extensive *in situ* carcinoma of the hypopharynx. No invasive tumour was found in this specimen.

Primary surgery

A non smoking 65-year-old woman who had a large piriform sinus carcinoma was the only patient treated by primary surgical excision This tumour had spread to the postcricoid region and extended into the ipsilateral hemilarynx The tumour had produced vocal cord fixation on that side by invading the intrinsic muscles and the cricoarytenoid joint Tumour had also invaded the thyroid and parathyroid glands and had metastasized to three of the 38 lymph nodes in the combined neck dissection specimen At the same surgical procedure this patient was found to have adenocarcinoma of the stomach which had also metastasized to lymph nodes

Surgery for irradiation failure

Two of the three patients in this category had multiple primary tumours of the hypopharynx (Table XV) Neither had a neck dissection The third patient in this category had a hypopharyngeal tumour treated by 5 000 rads of Cobalt 60 A laryngopharyngectomy was performed 7 months later and revealed a large multiregional tumour extending into the upper esophagus and involving the thyroid gland (Fig. 25) The tumour had metastasized to lymph nodes in the neck and upper mediastinum

Elective surgery following radiotherapy

Twenty five patients were treated by the combined method of therapy—20 received 3 000–5 500 rads of Cobalt 60 followed by elective surgery 6 weeks later five received 500–2 000 rads of Cobalt 60 followed by surgery usually within 48 hours.

Of the 20 patients receiving the full dose of irradiation 15 had *piriform sinus carcinoma* (Figs. 22, 23) and 5 had postcricoid tumours (Fig 24 /3 000 rads/) Neck dissection was performed on 16 and metastatic tumour was found in lymph nodes in 9 of these cases.

Of the 5 patients receiving the partial dose of irradiation followed by immediate surgery

Fig. 24. Postcricoid carcinoma. Coronal section through the cricoid plate of laryngo-pharyngectomy specimen. The tumour outlined by arrows occupies the postcricoid region to the left of the midline. This patient had radiotherapy (3 000 rads Cobalt 60) followed five weeks later by laryngopharyngectomy. A = arytenoid cartilage; C = cricoid cartilage; E = epiglottis; PS = piriform sinus; T = thyroid ala.

3 had piriform sinus tumours and 2 had multiregional lesions (Fig. 26). All 5 had combined neck dissection, and all except one (with a multiregional tumour, Fig. 26) had metastatic tumour in the neck nodes.

Spread of hypopharyngeal carcinoma

A characteristic feature of hypopharyngeal carcinomas is extensive submucosal spread (Hiroto 1963, Harrison, 1970). To a large extent the direction of spread and the structures invaded by hypopharyngeal carcinoma is determined by the site of origin of the neoplasm. The structures invaded by the tumours in our series are detailed in Table XVI. The patterns of spread in each of the three hypopharyngeal regions will be discussed separately.

Piriform sinus carcinoma

The piriform sinus is bounded superiorly by the pharyngoepiglottic fold, laterally by the inner surface of the thyroid cartilage, medially by the posterior surface of the aryepiglottic fold and the arytenoid and cricoid cartilages. Inferiorly it extends to the upper edge of the esophagus. In our series, five of the 19 tumours arising in the piriform sinus had extended laterally and appeared outside the laryngeal framework. Four of these penetrated the thyroid ala—this includes three which extended through the cricothyroid space as well—two with involvement of the adjacent thyroid gland. One additional tumour penetrated the cricothyroid space without cartilage involvement.

Of the 19 tumours in our series, 11 had

invaded by direct extension one or more of the laryngeal cartilages. Eight of these had invaded the thyroid ala (Fig 22) Invasion of the cricoid and arytenoid cartilage occurred less frequently and invasion of the epiglottic cartilage was observed in only one case It should be noted that in three with extensive involvement the tumour had invaded thyroid cricoid and arytenoid cartilages and that in all three the tumour penetrated into the crico-arytenoid joint space

When piriform sinus tumours extend medially to involve laryngeal structures, laryngeal function may be impaired and this may be the presenting clinical symptom Invasion of the intrinsic laryngeal muscles occurred in 8 piriform sinus carcinomas. Very extensive tumours tended to involve multiple muscle groups. Spread to the false vocal cord was observed in 3 and to the pre-epiglottic space in one The trachea was invaded by one tumour One very extensive tumour invaded the submaxillary salivary gland.

Combined neck dissection was performed in all 19 patients with piriform sinus carcinomas, and in one bilateral dissection was done Metastatic carcinoma was found in cervical nodes in 12 of the 19 Two had vascular and perineural invasion and four more had only perineural invasion

Comment A high proportion of piriform sinus tumours. (11 out of 19 in our series) had invasion of cartilaginous structures. This high frequency probably relates to the lack of anatomic barriers between the piriform sinus mucosa and the invaded cartilaginous structures. Another contributing feature may be the tendency for patients with piriform sinus carcinoma to present late in the course of their disease These same two features may explain the high incidence of intrinsic laryngeal muscle invasion (8 out of 19)

Ogura (1955) observed that piriform sinus tumours tend to be ulcerofungating and found little practical value in separating the tumours

Fig 36 Multiregional hypopharyngeal tumour This patient received a small dose of preoperative irradiation (500 rads Cobalt 60) just prior to laryngopharyngectomy and right neck dissection Despite the very extensive nature of this multiregional hypopharyngeal tumour all 48 cervical lymph nodes were free of metastatic tumour

[a] Atrophy of muscle after earlier operation for piriform sinus carcinoma.

vaded this muscle minimally but produced no detectable impairment of vocal-cord function.

Perineural invasion of the recurrent laryngeal nerve was seen fairly frequently in the hypopharyngeal carcinoma group with vocal cord fixation (five of nine), and in one patient with vocal cord fixation this invasion was the main cause.

Comment Vocal cord fixation was surprisingly frequent in hypopharyngeal carcinoma. In all nine of the 29 patients with impaired vocal cord function, hoarseness was the predominant symptom. It was the earliest symptom in four of these. Ogura (1955) noted vocal cord fixation frequently in *piriform sinus carcinomas* which involved the medial wall. Kirchner (1969) made similar observations: four of his 24 *piriform sinus carcinomas had vocal cord* fixation.

Metastasis to lymph nodes

As indicated above all 19 of the patients with piriform sinus tumors had neck dissections and 12 had positive cervical nodes at the time of laryngopharyngectomy. Only one of the 7 patients with postcricoid tumours had a combined neck dissection and he had *metastatic* tumour in the cervical nodes. All three of those with multiregional tumours had combined neck dissection—two had positive nodes.

Thus of 23 of the 29 patients with hypopharyngeal tumour who had combined neck dissection 15 had positive nodes.

A number of authors have noted the high incidence of nodal metastasis in hypopharyngeal carcinoma. Jorgensen (1971) indicated that in his material piriform sinus lesions had the highest incidence of nodal involvement (60%). Harrison (1970) noted that 17 of his 23 patients with piriform sinus carcinoma had positive lymph nodes at the time of surgery.

Harrison (1970) in a study of 21 patients with postcricoid carcinomas found 11 with positive nodes at the time of primary surgery. (Two patients developed metastasis later.) In our own series, infrequency of combined neck dissection *in postcricoid carcinomas* is striking —one out of seven.

Two explanations are advanced for the high incidence *of nodal metastasis in hypopharyngeal* tumours. These lesions tend to produce symptoms late and often the symptoms produced are related to laryngeal invasion with fixation of the vocal cord. In contrast to the laryngeal region, the piriform sinuses are richly supplied by lymphatic channels, which converge forward and exit via the lateral orifice of the thyroid membrane and drain into the upper and lower internal jugular chain of lymph nodes (Rouvière 1938 as quoted in MacComb & Fletcher 1967).

The thyroid gland was invaded in five of the 29 cases—three of them via direct extension through the thyroid ala. Ogura (1955) and Harrison *(1966–1968)* both have commented on the tendency of thyroid gland invasion by hypopharyngeal tumours.

THE EFFECT OF IRRADIATION

The review of 54 tumours from patients who received full-dose radiotherapy (mainly 5 500 rads), at Princess Margaret Hospital, Toronto *followed by* elective surgery afforded us an unique opportunity to study the patterns of response to irradiation of laryngeal or hypopharyngeal squamous-cell carcinoma.

as to their site of origin within the piriform sinus because most of these tumours involve both the medial and lateral walls. Tumours involving the medial wall tended to invade laryngeal structures producing vocal cord fixation This point was also emphasized by Kirchner (1969) Kirchner also indicated that when laryngeal invasion occurred the tumour often extends into the paraglottic space and then may clinically resemble a laryngeal carcinoma with transglottic distribution When such extension occurs, the tumour may escape through the cricothyroid space All of the above findings were confirmed in our own series.

In comparing the figures in Table XVI with Kirchner's series (1969) of similar tumours, we note that the thyroid cartilage was invaded in about the same frequency but that in our series, the cricoid and arytenoid cartilages and the cricoarytenoid joint space was invaded much more frequently

Harrison (1970) pointed out that tumours of the piriform sinus tend to be diagnosed late and had frequently metastasized to the cervical nodes. Our experiences would tend to confirm this observation.

Postcricoid carcinoma

The postcricoid region the posterior surface of the larynx, extends from the posterior surface of the arytenoid cartilage and its connecting folds to the inferior surface of the cricoid. It is bounded laterally by the piriform sinuses.

As one would expect three of the seven postcricoid tumours had invaded the cricoid cartilage and the posterior cricoarytenoid muscle (Fig 24) One of these was very extensive and involved other muscle groups the trachea and the adjacent thyroid gland.

One of the 7 patients with a postcricoid tumour had combined neck dissection and metastatic tumour was found in the cervical nodes

Vascular and perineural invasion was observed in two and in both the recurrent laryngeal nerve was involved

Posterior pharyngeal wall carcinoma

None of the tumours of this series was considered to have arisen in the posterior pharyngeal wall region.

Multiregional tumours

All three of the large hypopharyngeal tumours, classified as multiregional were characterized by extensive superficial growth and showed little tendency to involve the deeper structures of the larynx. However two of these had extended laterally through the lateral pharyngeal wall to invade the adjacent thyroid gland (Fig. 25 c) One of these patients had a bilateral neck dissection at the time of laryngopharyngectomy and had metastatic tumour on both sides of his neck. One had a neck dissection at the time of laryngopharyngectomy and had a neck dissection on the opposite side at a later date—metastatic tumour was present in lymph nodes in both of these procedures (Fig 25) The third patient who had a unilateral combined neck dissection had negative nodes (Fig 26)

Vocal cord fixation in hypopharyngeal carcinoma

Impaired mobility or fixation of one vocal cord was surprisingly frequent in our series It was noted in 9 of the 29 cases. The causes of this clinical finding are detailed in Table XVII There was interference with the intrinsic laryngeal muscles in all 9 either due to invasion by viable tumour or to fibrous replacement of the muscle after irradiation and eradication of the tumour In 3 piriform sinus tumours, the cricoarytenoid joint was invaded The most common muscle groups invaded were the posterior cricoarytenoid (Fig 24) and the thyroarytenoid Although the thyroarytenoid muscle was invaded as frequently as the posterior cricoarytenoid its involvement tended to be minor Four of the piriform sinus tumours and two of the postcricoid tumours invaded the posterior cricoarytenoid muscle (Fig 24) Another postcricoid tumour had in

Table XVII *Fixed vocal cord in hypopharyngeal carcinoma* (9 cases)

Perineural invasion	4	1

[a] Atrophy of muscle after earlier operation for piriform sinus carcinoma

vaded this muscle minimally but produced no detectable impairment of vocal-cord function.

Perineural invasion of the recurrent laryngeal nerve was seen fairly frequently in the hypopharyngeal carcinoma group with vocal cord fixation (five of nine) and in one patient with vocal cord fixation this invasion was the main cause.

Comment Vocal cord fixation was surprisingly frequent in hypopharyngeal carcinoma. In all nine of the 29 patients with impaired vocal cord function, hoarseness was the predominant symptom; it was the earliest symptom in four of these. Ogura (1955) noted vocal cord fixation frequently in piriform sinus carcinomas which involved the medial wall. Kirchner (1969) made similar observations: four of his 24 piriform sinus carcinomas had vocal cord fixation.

Metastasis to lymph nodes

As indicated above, all 19 of the patients with piriform sinus tumors had neck dissections and 12 had positive cervical nodes at the time of laryngopharyngectomy. Only one of the 7 patients with postcricoid tumours had a combined neck dissection and he had metastatic tumour in the cervical nodes. All three of those with multiregional tumours had combined neck dissection—two had positive nodes. Thus of 23 of the 29 patients with hypopharyngeal tumour who had combined neck dissection 15 had positive nodes.

A number of authors have noted the high incidence of nodal metastasis in hypopharyngeal carcinoma. Jorgensen (1971) indicated that in his material piriform sinus lesions had the highest incidence of nodal involvement (60%). Harrison (1970) noted that 17 of his 23 patients with piriform sinus carcinoma had positive lymph nodes at the time of surgery.

Harrison (1970) in a study of 21 patients with postcricoid carcinomas found 11 with positive nodes at the time of primary surgery. (Two patients developed metastasis later.) In our own series, infrequency of combined neck dissection in postericoid carcinomas is striking—one out of seven.

Two explanations are advanced for the high incidence of nodal mestastasis in hypopharyngeal tumours. These lesions tend to produce symptoms late and often the symptoms produced are related to laryngeal invasion with fixation of the vocal cord. In contrast to the laryngeal region, the piriform sinuses are richly supplied by lymphatic channels, which converge forward and exit via the lateral orifice of the thyroid membrane and drain into the upper and lower internal jugular chain of lymph nodes (Rouvière 1938 as quoted in MacComb & Fletcher 1967).

The thyroid gland was invaded in five of the 29 cases—three of them via direct extension through the thyroid ala. Ogura (1955) and Harrison (1966–1968) both have commented on the tendency of thyroid gland invasion by hypopharyngeal tumours.

THE EFFECT OF IRRADIATION

The review of 54 tumours from patients who received full-dose radiotherapy (mainly 5 500 rads), at Princess Margaret Hospital, Toronto, followed by elective surgery afforded us an unique opportunity to study the patterns of response to irradiation of laryngeal or hypopharyngeal squamous-cell carcinoma.

Fig 7 No residual tumour following radiotherapy. This patient received a full dose of radiotherapy (5 500 rads Cobalt 60) followed six weeks later by laryngectomy and left neck dissection. There was no metastatic tumour in the cervical lymph nodes.

(*a*) Gross photograph of the laryngectomy specimen illustrating the obliteration of the laryngeal ventricle on the left side.

Hypopharyngeal carcinoma (20)	8	7	5	
Neck dissections	8 (5)	4 (2)	4 (2)	

Patterns of tumour response

Full course of radiotherapy

Histologically similar tumours make four distinctly different responses to identical irradiation therapy (Table XVIII). The following patterns were noted in 34 patients with laryngeal and 20 with hypopharyngeal tumours who had the full radiotherapy dose followed by surgery six weeks later.

A. *No residual tumour* (Fig. 27). Six of the 34 (18) in whom laryngeal carcinomas were treated by the combined method had no residual tumour in the laryngectomy specimen. Of the six, three had primary glottic tumours (Fig. 27) and three had primary supraglottic tumours. Five of these six had neck dissection and all were free of metastatic tumour.

Of the 20 patients with hypopharyngeal lesions eight (40) had no residual tumour at the primary site at laryngopharyngectomy. Seven of these tumours were piriform sinus lesions and one originated in the postericoid region. All eight patients had a neck dissection. The postcricoid tumour and four of the piriform sinus tumour had metastasized to neck nodes at the time of surgery.

replaced by fibrous connective tissue (arrow) with obliteration of the laryngeal ventricle. Note the joints between the corpus and the major cornua of the hyoid bone (H). C cricoid cartilage T thyroid ala.

( ) Photomicrograph to illustrate moderate post-radiation atrophy of the seromucous glands of the submucosa of the false vocal cords.

(*d*) Photomicrograph of the scarred area totally replacing the tumour. Note the moderate chronic inflammatory infiltrate and the squamous metaplasia of the ducts of the submucosal glands in the upper right corner.

Comment. With respect to the primary tumour it was eradicated and replaced by fibrous connective tissue twice as often in the hypopharyngeal as in the laryngeal tumours. However none of the laryngeal tumours had metastasized to the regional nodes at the time of surgery but, in the combined neck dissection specimens, five of the hypopharyngeal tumours (63%) had already spread to the cervical nodes.

B. *Fibrosis with scattered tumour nests* (Fig. 28). Twelve of the 34 patients with laryngeal tumours (35%) had extensive fibrosis of the tumour area in which scattered nests of tumour were identified. In the usual pattern of response that we observed tumour nests were scattered evenly throughout the whole of the fibrosed area. In a small number of cases, there were very few tumour nests and these occupied only small portions of the fibrosed area and large areas of fibrosis were free of tumour. A main feature in this group was the presence of numerous foreign-body granulomas with giant cells surrounding residual keratin material.

Of the 12 laryngeal lesions, 9 were primary glottic tumours, three were primary supraglottic tumours (Fig. 28). Six neck dissections were performed in the glottic group and two contained metastatic carcinoma. Two neck dissections were performed in the supraglottic group and both were positive.

Seven of the 20 hypopharyngeal tumours (35%) showed scattered nests of tumour in fibrous connective tissue—*four of these* were piriform sinus primaries and three were postcricoid primaries. All four patients with piriform sinus tumours had combined neck dissec

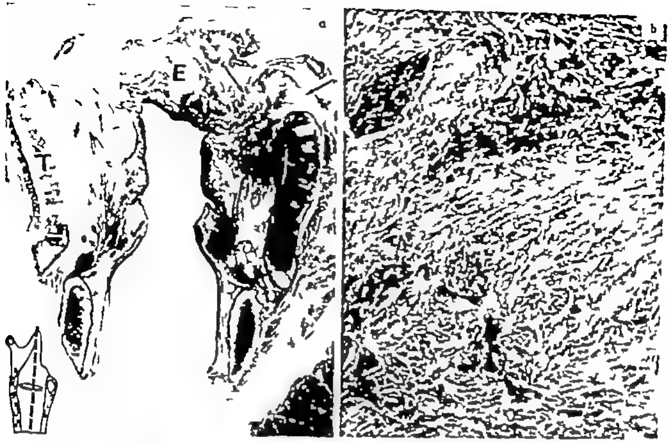

Fig 28 Fibrosis with scattered tumour nests following radiotherapy This patient had a full dose of radiotherapy (5 500 rads Cobalt 60) followed 7 weeks later by laryngectomy and neck dissection. Metastatic carcinoma was found in the cervical lymph nodes.

(*a*) Coronal section from the total laryngectomy specimen at the level of the vocal process. There is extensive fibrosis outlined by the arrows occupying the right aryepiglottic fold and adjacent right piriform sinus. C = cricoid cartilage; E = epiglottis; T = thyroid cartilage

(*b*) Photomicrograph from the fibrosed area illustrated in Figure 28 *a* illustrating nests of tumour cells surrounded by dense fibrous connective tissue

tions—two had positive nodes. None of the patients with postcricoid carcinomas had combined neck dissections.

Comment It appears that about one third of laryngeal and one third of hypopharyngeal tumours exhibit fibrosis with scattered tumour nests. In both groups, about one-third of the tumours had metastasized to cervical nodes at the time of surgery

Assessment of the viability of these tumour nests was extremely difficult We attempted to assess the viability of these nests using an autoradiographic technique (Briant et al 1971) after perfusing the whole larynx under hyperbaric conditions immediately after removal from the patient This technique did not prove conclusively whether these nests were viable or not It did, however establish that whole organ perfusion using this method is feasible though technically difficult The technique is no longer used in our laboratory

C *Minimal tumour response* (*Fig 29*). In these tumours (19) there was minimal tumour necrosis and minimal fibrosis. The size of the tumour in the operative specimen corresponded closely to that observed clinically both before radiotherapy and before operation

Fourteen of the 34 laryngeal tumours (41) exhibited minimal response—nine were glottic primaries, 4 were supraglottic and 1 was subglottic *Six neck dissections were performed in* patients in the glottic group—two had positive nodes. Three neck dissections were performed in the supraglottic groups—one had positive nodes. The patient with the subglottic primary did not have a neck dissection

Five of the 20 hypopharyngeal tumours

Fig. 79 Minimal tumour response to radiotherapy This patient had a full dose of radiotherapy (5 500 rads Cobalt 60) followed by laryngectomy and neck dissection Metastatic carcinoma was present in the cervical lymph nodes

( ) Coronal section of the total laryngectomy specimen taken through the anterior portion of the arytenoid cartilages The very large tumour (arrows) occupies the left hemilarynx and partially destroys the arytenoid cartilage (A), thyroid cartilage (T), cricoid cartilage (C), and has spread outside the laryngeal framework through the cricothyroid space. E = epiglottis, THY = thyroid gland

(*b*) Photomicrograph of the tumour illustrating large clumps of tumour cells with moderate adjacent fibrous connective tissue A biopsy of the tumour taken prior to the radiotherapy showed an identical histologic pattern

(25) exhibited minimal response to irradiation—four were piriform sinus primaries and one was postericoid All four of the piriform sinus lesions had neck dissection— two had positive nodes The patient with the post cricoid tumour did not have a neck dissection

Comment Minimal tumour response was observed nearly twice as often in the laryngeal tumours (41 %) as in the hypopharyngeal tumours (25 %) Only three of the 14 laryngeal tumours (1 %) had metastasized at the time of operation while two of the five hypopharyngeal tumours (40 %) had done so

We are convinced that the lack of response to radiotherapy exhibited by these tumours is a manifestation of the biological behaviour of the tumour Different biochemical characteristics of the tumour seem to influence its radiosensitivity (Tokhadze, 1966 Paavolainen, 1970 Tachibana, 1971)

D *Residual central tumour* We hoped that, following radiotherapy the viable tumour would shrink to a small central focus that could be more easily and safely resected by the surgeon. This pattern of response was rarely seen. In only two laryngeal carcinomas was the residual tumour confined to a small focus in the mucosa and submucosa overlying an area of extensive fibrosis. Both of these lesions were glottic primaries. Combined neck dissection was performed on one of these two patients and the cervical nodes were free of tumour

None of the hypopharyngeal tumours exhibited a central residual tumour

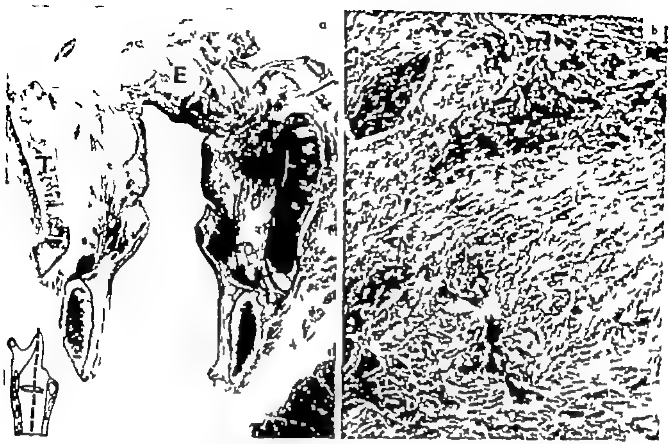

Fig 28 Fibrosis with scattered tumour nests following radiotherapy This patient had a full dose of radiotherapy (5 500 rads Cobalt 60) followed 7 weeks later by laryngectomy and neck dissection Metastatic carcinoma was found in the cervical lymph nodes.

(25%) exhibited minimal response to irradiation—four were piriform sinus primaries and one was postericoid. All four of the piriform sinus lesions had neck dissection— two had positive nodes. The patient with the postericoid tumour did not have a neck dissection.

Comment. Minimal tumour response was observed nearly twice as often in the laryngeal tumours (41) as in the hypopharyngeal tumours (25). Only three of the 14 laryngeal tumours (21%) had metastasized at the time of operation while two of the five hypopharyngeal tumours (40%) had done so.

We are convinced that the lack of response to radiotherapy exhibited by these tumours is a manifestation of the biological behaviour of the tumour. Different biochemical characteristics of the tumour seem to influence its radiosensitivity (Tokhadze 1966, Paavolainen, 1970, Tachibana, 1971).

D. *Residual central tumour.* We hoped that, following radiotherapy the viable tumour would shrink to a small central focus that could be more easily and safely resected by the surgeon. This pattern of response was rarely seen. In only two laryngeal carcinomas was the residual tumour confined to a small focus in the mucosa and submucosa overlying an area of extensive fibrosis. Both of these lesions were glottic primaries. Combined neck dissection was performed on one of these two patients and the cervical nodes were free of tumour.

None of the hypopharyngeal tumours exhibited a central residual tumour.

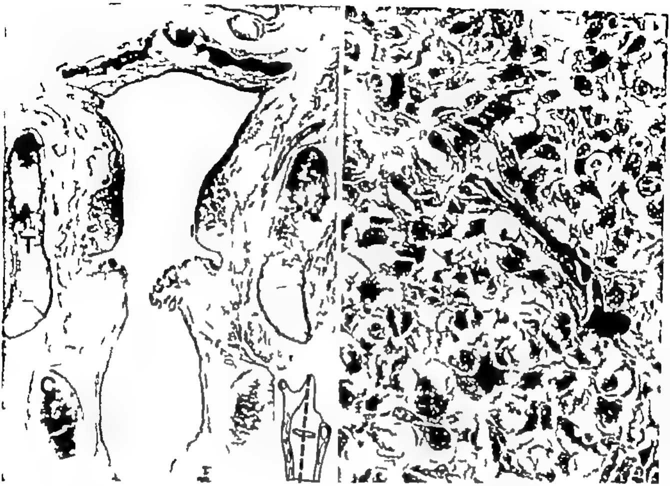

Fig 30 Acute irradiation changes This patient was receiving a full course of radiotherapy for a vocal cord tumour After he had received 3 000 rads of Cobalt 60 he developed thrombosis of his right carotid artery and died

(*a*) Coronal section through the larynx removed at autopsy taken at the level of the middle third of the vocal cords. A well circumscribed tumour mass occupied the free margin of the right vocal cord C = cricoid cartilage, E = epiglottis, T = thyroid ala.

(*b*) High power photomicrograph of the tumour illustrating acute irradiation changes. The tumour cell nuclei are irregular in size and shape with many giant forms. There are many "balloon cells" with vacuolated cytoplasm and many pyknotic nuclei

Acute irradiation changes

One patient selected for combined therapy died during irradiation At the time of death he had received a tumour dose of 3 000 rads beginning three weeks before and ending five days before death. At autopsy the tumour showed large areas of necrosis with associated acute inflammatory reaction and surface ulceration The tumour's most striking feature was the extremely bizarre morphology of the individual cells. Balloon cells were common with marked vacuolation of the cytoplasm The nuclei of all the tumour cells tended to be irregular and pyknotic Mitotic figures were numerous and abnormal mitoses were frequent (Fig 30)

Comments The acute effect of irradiation on squamous-cell carcinoma has been well described by authors interested in radiation pathology and need not be elaborated upon here (Rubin & Casarett, 1968 Ackerman & del Regato 1970 Skolnik et al. 1970)

Immediate preoperative irradiation

Nine laryngeal and five hypopharyngeal tumours received immediate preoperative irradiation of 500–2 000 rads In most cases the in

terval between irradiation and operation was 24 to 48 hours. In examining the operative specimens from these 14 patients no histopathological features were observed which could be attributed solely to the effects of irradiation.

The acute oedema and the early inflammatory response which others described as an immediate reaction to irradiation therapy was not seen in these cases.

Comment. As was indicated in the introduction, the rationale of using low-dosage immediate preoperative radiotherapy is to improve the cure rate by achieving a moderate degree of tumour-cell sterilization and by closing off lymphatic channels from the tumour area. This type of therapy does not complicate the surgical procedures nor delay wound healing. (Both of these problems are encountered after *full* dose radiotherapy.) In animal experiments this type of therapy decreases distant metastasis and local recurrences (Moss & Brand, 1969). Also similar benefits have been recorded in human tumours after this type of therapy (Hemschka et al., 1966), but most reports on the clinical side have been inconclusive (Moss & Brand, 1969). Our own cases receiving immediate preoperative radiotherapy exhibited no histopathologic features that distinguished them from those which were operated upon without irradiation.

Comment on the effect of irradiation on the primary tumour

Fifty-four of our patients received full-dose radiotherapy combined with surgical resection six weeks later. We hoped that radiotherapy would shrink and sterilize the tumour mass, thus making surgical resection easier and safer. Even though in many cases there was significant shrinkage which could be observed clinically, scattered foci of tumour cells persisted even in the periphery of such tumours. Such nests were present in 19 of the 54 tumours. Goldman et al. (1972), and Skolnik et al. (1970) all described a similar response to irradiation. Because of the difficulties to distinguish between nonviable tumour cells and those that are viable and capable of reproduction (Friedman & Goldman 1969, Briant et al., 1971) it is impossible to predict on histologic ground which of these tumours would recur at the primary site. We therefore support the contention of Goldman et al. (1970) that, when operating on such patients, either electively during combined therapy or for irradiation failure, all of the tissue previously involved by tumour must be removed. This is particularly important when using partial, voice conservation surgery following irradiation failure. Metastatic spread to neck nodes occurred in about one-third of the patients in the group with fibrosis and scattered tumour nests, and there was no significant difference in the incidence of metastatic spread between laryngeal and hypopharyngeal tumours.

The tumour at the primary site was eradicated by irradiation twice as often in the hypopharyngeal as in the laryngeal tumours. It should be noted, however, that the tumours had already spread to the neck nodes at the time of surgery in two thirds of the hypopharyngeal lesions, but not in any of the laryngeal tumours.

Nineteen of the 54 tumours showed minimal tumour response. We were surprised to find that this included more than 40% of laryngeal tumours and 25% of hypopharyngeal tumours. Presumably all of these patients would eventually have required surgery for residual or recurrent tumour at the primary site, if they had not been in the combined therapy program.

The grading (Broders') of the tumours in the pre-operative irradiation group followed the distribution of the whole series. Referring to grading, no distinct pattern of response to irradiation could be noted.

Irradiation effect on other tissues

For comparison in the study of irradiation effects we had a number of non-tumour la-

Comment on the effect of irradiation on the primary tumour

Fifty-four of our patients received full-dose radiotherapy combined with surgical resection six weeks later. We hoped that radiotherapy would shrink and sterilize the tumour mass, thus making surgical resection easier and safer. Even though in many cases there was significant shrinkage which could be observed clinically, scattered foci of tumour cells persisted even in the periphery of such tumours. Such nests were present in 19 of the 54 tumours. Goldman et al. (1972) and Skolnik et al. (1970) all described a similar response to irradiation. Because of the difficulties to distinguish between nonviable tumour cells and those that are viable and capable of reproduction (Friedman & Goldman 1969, Briant et al. 1971), it is impossible to predict on histologic ground which of these tumours would recur at the primary site. We therefore support the contention of Goldman et al. (1970) that, when operating on such patients, either electively during combined therapy or for irradiation failure, all of the tissue previously involved by tumour must be removed. This is particularly important when using partial, voice conservation, surgery following irradiation failure. Metastatic spread to neck nodes occurred in about one-third of the patients in the group with fibrosis and scattered tumour nests, and there was no significant difference in the incidence of metastatic spread between laryngeal and hypopharyngeal tumours.

The tumour at the primary site was eradicated by irradiation twice as often in the hypopharyngeal as in the laryngeal tumours. It should be noted, however, that the tumours had already spread to the neck nodes at the time of surgery in two thirds of the hypopharyngeal lesions, but not in any of the laryngeal tumours.

Nineteen of the 54 tumours showed minimal tumour response. We were surprised to find that this included more than 40% of laryngeal tumours and 25% of hypopharyngeal tumours. Presumably all of these patients would eventually have required surgery for residual or recurrent tumour at the primary site, if they had not been in the combined therapy program.

The grading (Broders') of the tumours in the pre-operative irradiation group followed the distribution of the whole series. Referring to grading, no distinct pattern of response to irradiation could be noted.

Irradiation effect on other tissues

For comparison in the study of irradiation effects we had a number of non-tumour la-

rynges removed at autopsy and also all specimens from patients treated by primary surgery

In those patients who received 500 to 2 000 rads with surgery within 48 hours, none of the irradiation effects on other tissues that are described below were observed.

In the single autopsy of the patient who died during radiotherapy we found total atrophy of the hemopoietic elements in the bone marrow cavity but not the epithelial, submucosal gland and vascular changes described below

These changes were found in all patients who received 5 500 rads, either in the combined therapy group or in the irradiation failure group

Epithelial changes

Squamous epithelium is relatively resistant to irradiation change. We have however noted acanthosis and hyperkeratosis much more frequently in the irradiated larynges than in those treated by primary surgery The dysplasia present in the squamous epithelium adjacent to many of the tumours, was not attributed to irradiation effect

The ciliated columnar (respiratory) epithelium is far more susceptible to the effects of irradiation (Alexander 1963 Manara & Mira 1968) Metaplasia of respiratory—type epithelium to stratified squamous epithelium—was frequent especially in the false vocal cords and in the laryngeal ventricles.

Although squamous metaplasia is frequently seen in the false vocal cords of heavy smokers (Auerbach et al. 1970) we have never observed such changes in the laryngeal ventricle in the absence of previous irradiation Despite individual variation the above noted epithelial changes were observed in most of the specimens from both the combined therapy group and the irradiation failure group

Submucosal gland changes

The submucosa of the supraglottic and subglottic regions is rich in seromucinous glands These glands are very susceptible to irradiation and the serous component is more susceptible than the mucinous component (Manara & Mira, 1968 Ackerman, 1972) The glands in our material showed varying degrees of acinar atrophy chronic mononuclear inflammatory infiltration squamous metaplasia of the ductal epithelium and fibrous replacement (Fig. 27 c d) Squamous metaplasia of the ductal epithelium has also been described by Skolnik et al (1970) In the group of cases receiving the combined therapy with full dose of irradiation squamous metaplasia of the ductal epithelium and inflammatory infiltration were prominent In the irradiation failure group acinar atrophy with submucosal fibrosis was more frequent

Blood vessel changes

Important changes occur in the vascular bed following irradiation therapy (Alexander 1963 Manara & Mira 1968 Ackerman 1972) The vascular endothelium is the most susceptible portion of the vessel. Endothelium is vulnerable if the dose of irradiation exceeds 1 ?00 rads (Alexander 1963) The damage is usually irreversible. Electron microscopy studies have shown "an endothelial swelling and detachment with splitting and swelling of the basement membrane in the subendothelial space and in the media (Ackerman 1972) The endothelial cells undergo dissolution and fibrin thrombi are deposited followed by a complete thrombosis of the lumen and often recanalization at a later date In man the pathognomic sign of radiation effect is the presence of subintimal foam cells in moderate sized vessels (Ackerman 1972)

In our material postirradiation changes were present in both the arteries and the veins —those in the arteries predominating There was no significant difference between the combined therapy group and the irradiation failure group The most prominent and most common change was intimal proliferation with partial obliteration of the lumen More severe damage totally obliterated the luman and there was recanalization of the arterioles. The vessels

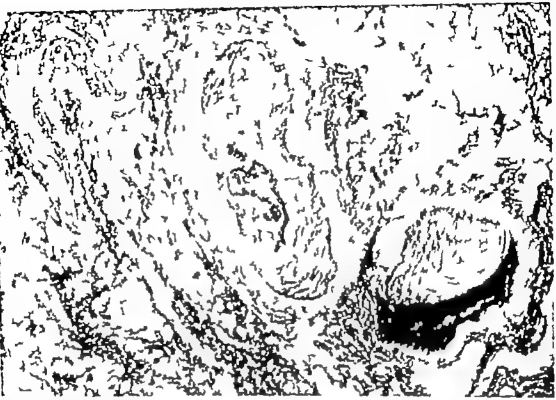

Fig 31 Post irradiation blood vessel changes Photomicrograph of prelaryngeal vessels illustrating marked intimal proliferation, splitting of the internal elastic lamina and fibrosis of the adventitia with virtually complete obliteration of the vessel lumen Th patient received full dose of radiotherapy (5 500 rads of Cobalt 60) for carcinoma of the right vocal cord Seven years later partial laryngectomy was performed for recurrent tumour at the anterior commissure

containing elastic tissues exhibited varying degrees of fragmentation and replacement of the elastica Adventitial fibrosis was also common (Fig 31)

Cartilage changes

There were no gross changes in the cartilaginous framework of the larynx that could be attributed solely to irradiation. Chondronecrosis was occasionally seen in association with infection within the cartilaginous portions of the framework (Fig 32)

Alexander (1963) noted that in the absence of infection, cartilage shows very little change after irradiation If the covering of the cartilage remains intact, it resists large doses of irradiation Many authors, however have noted that if the perichondrium is breached by operative trauma or tumour invasion, chondronecrosis frequently ensues (Goodrich & Lenz, 1948 Albrecht, 1951 Oeser 1951 Zange 1951 Vogel & Bogasch, 1955 Parker 1962 Rubin & Casarett, 1968). Lederman (1970) noted that a mild perichondritis was occasionally encountered usually after a history of respiratory infection.

Bony changes

In the adult, to a greater or lesser degree, the so-called cartilages" that make up the laryngeal framework are composed of trabecular bone with marrow containing central portions. This ossification of the thyroid ala, the cricoid and the arytenoids usually follows a specific pattern and has been studied by many radiologists because it has great importance in inter

rynges removed at autopsy and also all specimens from patients treated by primary surgery

In those patients who received 500 to 2 000 rads with surgery within 48 hours, none of the irradiation effects on other tissues that are described below were observed

In the single autopsy of the patient who died during radiotherapy we found total atrophy of the hemopoietic elements in the bone-marrow cavity but not the epithelial submucosal gland and vascular changes described below

These changes were found in all patients who received 5 500 rads, either in the combined therapy group or in the irradiation failure group

Epithelial changes

Squamous epithelium is relatively resistant to irradiation change. containing elastic tissues exhibited varying degrees of fragmentation and replacement of the elastica. Adventitial fibrosis was also common (Fig. 31).

Cartilage changes

There were no gross changes in the cartilaginous framework of the larynx that could be attributed solely to irradiation. Chondronecrosis was occasionally seen in association with infection within the cartilaginous portions of the framework (Fig. 32).

Alexander (1963) noted that, in the absence of infection, cartilage shows very little change after irradiation. If the covering of the cartilage remains intact, it resists large doses of irradiation. Many authors, however, have noted that if the perichondrium is breached by operative trauma or tumour invasion, chondronecrosis frequently ensues (Goodrich & Lenz, 1948; Albrecht, 1951; Oeser, 1951; Zange, 1951; Vogel & Bogasch, 1955; Parker, 1962; Rubin & Casarett, 1968). Lederman (1970) noted that a mild perichondritis was occasionally encountered usually after a history of respiratory infection.

Bony changes

In the adult, to a greater or lesser degree, the so-called "cartilages" that make up the laryngeal framework are composed of trabecular bone with marrow containing central portions. This ossification of the thyroid ala, the cricoid and the arytenoids usually follows a specific pattern and has been studied by many radiologists because it has great importance in inter

Fig 32 Chondronecrosis following radiotherapy This patient received a full course of radiotherapy (5 500 rads of Cobalt 60) for a glottic tumour with subglottic extension Six months later a total laryngectomy was performed for persistent airway obstruction and extensive subglottic oedema.

(*a*) Coronal section of the total laryngectomy specimen through the posterior third of the vocal cords. There is extensive destruction of the cricoid cartilage (C) with marked obstruction of the airway by fragments of residual cartilage and granulation tissue (arrows) No residual tumour was found in this specimen.

(*b*) Coronal section of the laryngectomy specimen through the posterior cricoid plate The cricoid cartilage (C) has been largely destroyed and there is very extensive acute and chronic inflammation as indicated by the arrows. A = arytenoid cartilage T = thyroid ala, THY = thyroid gland.

pretation of soft tissue films (Scheier 1899 1901–1902 1909 Baclesse 1949) Occasionally especially in the elderly centres of ossification also appear in the cartilaginous tracheal rings.

The changes, which we have seen in the bony portions of laryngectomy specimens can be attributed to a combination of irradiation effect and associated infection These changes usually take the form of osteomyelitis with sequestrated bone fragments and a fistulous tract draining to the laryngeal mucosa Similar changes have been described by other authors (Parker 1962 Rubin & Casarett 1968)

Bone marrow changes

The susceptibility of hemopoietic tissues to irradiation is well known and the atrophy of the hemopoietic elements within marrow containing bone is one of the earliest and most predictable signs of even small doses of irradiation (Rubin & Casarett 1968 Ackerman & del Regato 1970)

The marrow spaces in the laryngeal framework of those patients who had no irradiation contain abundant hemopoietic tissue All those who received 5 500 rads (including the combined therapy and irradiation failure groups) showed marked atrophy or complete absence of the hemopoietic tissue with replacement by fatty marrow Actual fibrosis of the marrow cavity was seen only in association with tumour involvement of the adjacent bone In a few cases, residual fragments of active hemopoietic tissue persisted in the marrow at the margins of the field of irradiation

Muscle changes

Striated muscle is relatively radioresistant. Rubin and Casarett (1968) described secondary changes in striated muscle following oedema, inflammation and vascular disturbance which may be attributed indirectly to irradiation. In addition, Alexander (1963) described fatty degeneration and Zenker's degeneration with hyaline bridges, loss of striation, and scattered or absent nuclei. Manara & Mira (1968) noticed waxy degeneration and fragmentation of single fibers followed by connective tissue proliferation.

These degenerative changes were not observed in our cases. Neurogenic atrophy following operative denervation or tumour invasion of nerve was however not uncommon.

OTHER FINDINGS

Mucosal dysplasia

Dysplastic changes in the laryngeal mucosa varying from mild to moderate to severe to *in situ* carcinoma have long been recognized (Broders, 1932, Altman et al. 1952, Miller & Fisher 1953, Kleinsasser & Heck, 1959, Holinger & Schild, 1965, Bridger & Nassar 1971, McNelis & Esparza, 1971). The association of *in situ* carcinoma with an invasive carcinoma either in immediately adjacent mucosa or elsewhere in the larynx has been noted by a number of authors (Smitman, 1945, Brunner 1950, Miller & Fisher 1953, Stout 1953, Kleinsasser & Heck, 1959, Rabbett, 1962, Daly & Valerin, 1969, Miller 1970).

Dysplastic mucosal changes were present in 14 of our 139 cases—11 in patients with laryngeal carcinoma and three in those with hypopharyngeal carcinoma (Fig. 33). These changes varied from mild focal atypia to widespread severe dysplasia and *in situ* carcinoma. The most severe changes were in the mucosa immediately adjacent to foci of invasive tumor. In seven of the 14 irradiation therapy had been employed four months to three years previously in these, some of the atypia may be attributed to the irradiation.

The presence of multicentric or widespread dysplastic changes within the larynx and hypopharynx may account for the multiple primary malignancies encountered in the laryngeal and hypopharyngeal area. (Wynder et al., 1956, Rabbett, 1962, Helner 1967).

In four patients multiple primary squamous carcinomas were present in the laryngeal or hypopharyngeal mucosa—two were laryngeal and two were hypopharyngeal. One of the patients with laryngeal carcinoma had synchronous transglottic and epiglottic tumours, both invasive but with no connections. The other three cases had metachronous tumours.

Other primary malignancies

In addition to noting the high frequency of multiple primary tumours within the larynx and hypopharynx, a number of authors have described laryngeal or hypopharyngeal tumours, associated with other malignancies elsewhere in the body. The association of laryngeal primaries with tumours of the lower respiratory tract and bronchi has been noted by Wynder et al. (1956), Norris (1959), Holinger et al. (1961), Cahan et al. (1962), Knudson et al. (1965), Shaw (1965), Tiche (1966), and Auerbach et al. (1970). Shaw (1965) in a study of 306 patients with laryngeal carcinoma found that 23 (7%) had multiple primary malignancies—one third of these in the bronchial tree. In contrast tumours of the hypopharynx seem to be associated more with lesions of the gastrointestinal (GI) tract (Ballantyne, 1967, Stefani & Eells, 1971). Jacobsson (1951) studied 322 patients with hypopharyngeal carcinoma and in the 67 who survived more than two years, 10 developed a second primary tumour—7 of these were in the digestive tract.

Four of the patients in our series had primary tumours outside of the laryngeal—hypopharyngeal area. A previously treated squamous-cell carcinoma of the oral cavity was noted in a patient with piriform sinus carcinoma. Synchronous basal cell carcinoma of the lip and adenocarcinoma of the stomach were present in two patients, both with hypo-

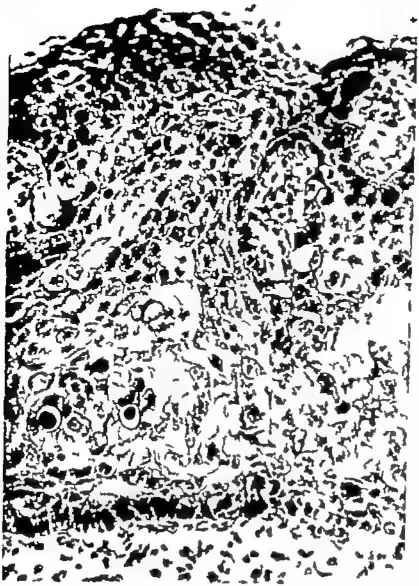

Fig 33 Severe dysplasia and carcinoma-in-situ High power photomicrograph illustrating severe dysplasia and in situ carcinoma This illustration is representative of very widespread in situ carcinoma which was present over large areas of the hypopharyngeal mucosa in a patient who also had two separate invasive carcinomas, one of the post cricoid region and the other of the lateral pharyngeal wall This patient had radiotherapy for thyrotoxicosis 34 years prior to laryngopharyngectomy Metastatic carcinoma was present at the time of surgery in cervical lymph nodes from both sides of the neck

pharyngeal primaries An occult adenocarcinoma of the thyroid gland was discovered in the surgical specimen from a patient with laryngeal carcinoma. With reference to thyroid carcinoma 111 lobes of thyroid gland were removed from 99 patients in this series and we discovered only this solitary occult tumour The incidence of occult carcinoma of the thyroid is said to be much higher than this would suggest (Key 1971)

Anatomic variations

Joints in the hyoid bone Twenty nine patients had a cartilaginous joint space lined by synovium in one or both sides of the hyoid between the corpus and the major cornu (Fig. 27) A few cases of these had an additional joint between the corpus and the minor cornu. This finding was also noted by Goldman et al (1966) in a series of serially sectioned larynges.

Thyroglossal duct remnants. In nine patients, remnants of the thyroglossal duct were present in the prelaryngeal tissues between the thyroid isthmus and the hyoid bone Most remnants showed only microscopic foci of thyroid acini, but the occasional patient had nodules of thyroid parenchyma up to 1 cm in diameter

Thyroid cartilage abnormality Two patients exhibited extreme thickening of one of the thyroid alae but there was no apparent cause for the unilateral hypertrophy

Conclusions

Our knowledge of the anatomy and tumour pathology of the larynx and hypopharynx has been increased by serially sectioned whole organ laryngectomy and laryngopharyngectomy specimens. However we must take into account when drawing our conclusions that we are dealing with a selected material. The majority of our cases were residual and recurrent tumours after previous radiotherapy or were advanced carcinomas treated by preoperative irradiation or in some cases primary surgery. A few patients received primary partial laryngectomies for limited carcinomas.

The surface extension of the tumours in many cases represents only the top of the iceberg, which may explain the great difficulties involved in assessing the tumours—despite careful indirect, and direct laryngoscopy and hypopharyngoscopy supported by radiological examinations. Neither of these methods renders accurate information as to the deep extension of the tumours. The difficulties in assessing correctly the extension of tumours are even greater after previous irradiation. "Post-irradiation" oedema, and sometimes an intact overlying mucosa, can totally confuse the picture. Fixation of the structures, and especially vocal-cord fixation, is the main clinical sign of a deep invasion of tumour. In a great percentage (over 50 %) of the cases with vocal-cord fixation, the tumour extended outside the laryngeal framework. Therefore we consider vocal-cord fixation a contraindication to partial surgery, especially if it occurs after previous radiotherapy. In these cases a narrow-field laryngectomy skeletonizing the thyroid cartilage has obvious risks, and a wide-field laryngectomy has to be recommended.

The site of origin determines the type of growth and spread of the tumour within the larynx and hypopharynx. The primary glottic tumours extend more often vertically than horizontally. The tumours spread mostly outside the larynx through the points of weakness in the laryngeal framework. The glottic tumours spread most frequently outside the larynx in the anterior commissure region through cartilage or when extending subglottically through the cricothyroid membrane. In the anterior commissure region the mucosa lies closer to the thyroid cartilage than anywhere else along the cords. There is only a thin layer of submucosa separating the mucosa from the "anterior commissure tendon" that intervene with the underlying cartilage. The tumour just as easily spreads downward and out through the cricothyroid membrane.

Many of the larger tumours also spread laterally through the cricothyroid space and through the thyroid ala. This type of spread is prominent for tumours with involvement of both vocal and false vocal cords—"transglottic" distribution. When the cartilages are invaded it is the ossified portions that are first replaced by tumour.

Supraglottic tumours are in many cases characterized by pushing margins, a great tendency to invade the pre-epiglottic space (PES) with or without epiglottic cartilage destruction. At operation this space should always be included in the laryngectomy specimen in supraglottic tumours and in all carcinomas occupying the dorsal (laryngeal) surface of the epiglottis. We found that the supraglottic tumours in our material had a strikingly high tendency to invade the glottic region (6 out of 25) which is a factor of great importance, when performing partial supraglottic laryngectomies.

The subglottic group of tumours, which was very small, had some common characteristics. They were flat, circumferential and all penetrated the conus elasticus to invade

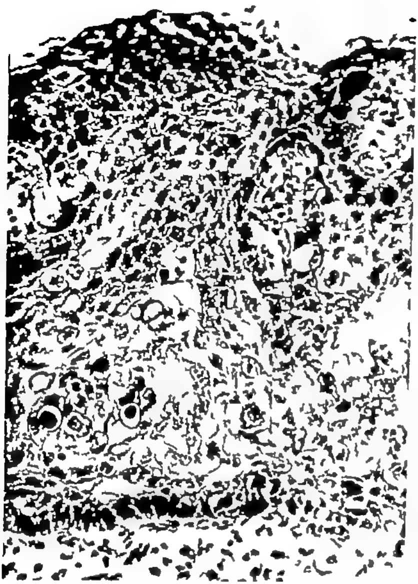

Fig 33 Severe dysplasia and carcinoma-in situ High power photomicrograph illustrating severe dysplasia and in situ carcinoma This illustration is representative of very widespread in situ carcinoma which was present over large areas of the hypopharyngeal mucosa in a patient who also had two separate invasive carcinomas, one of the post cricoid region and the other of the lateral pharyngeal wall This patient had radiotherapy for thyrotoxicosis 54 years prior to laryngopharyngectomy Metastatic carcinoma was present at the time of surgery in cervical lymph nodes from both sides of the neck

Summary

Whole-organ serial sectioning provides an ideal method of studying the growth and spread of tumour. We have used this method to study 139 squamous-cell carcinomas arising in the larynx and hypopharynx—110 in the larynx and 29 in the hypopharynx.

The incidence of laryngeal carcinoma parallels the incidence of malignant tumours arising in the tracheobronchial tree—both are rising. Laryngeal tumours tend to be moderately well-differentiated, squamous-cell carcinomas (Broders' grade II). The growth and spread of laryngeal tumours is largely determined by the site of the primary tumour. We have made a serious effort to define and delineate the anatomic boundaries as assessed histopathologically of the three regions of the larynx—glottic, supraglottic and subglottic. There are a number of physical (anatomic) barriers within the larynx, which tend to limit the spread of tumour and these form a number of anatomic compartments—the more important ones include Reinke's space, pre-epiglottic space (PES) and the paraglottic space.

Seventy-three of the 110 laryngeal tumours arose in the glottic region. We consider the conus elasticus to be the histopathological boundary between the glottic and subglottic regions, and the lateral angle of the laryngeal ventricle to be the boundary between the glottic and supraglottic regions. Vertical extension of these tumours (to the supraglottic and/or subglottic regions) occurred much more frequently than horizontal extension (to the opposite hemilarynx). Glottic tumours tend to be confined for long periods by the laryngeal cartilaginous framework. When these tumours spread outside the larynx, they do so through the points of weakness in the laryngeal framework. Tumours involving the anterior commissure region of the larynx penetrate the cricothyroid membrane after extending subglottically. More than 75% of the glottic tumours extending outside the larynx used this portal of exit. These tumours often invade and penetrate the adjacent lower border of the thyroid cartilage. Further posteriorly glottic tumours spread laterally to penetrate the cricothyroid space and extend outside the laryngeal framework. This finding was particularly noted in those large glottic tumours that had extended to the supraglottic and subglottic regions. Here too, the adjacent thyroid ala and upper border of the cricoid cartilage were often invaded and penetrated.

Vocal-cord fixation was a common clinical finding in our series (32 out of the 73 cases with glottic primaries) and we studied the histopathological causes of the fixation. Invasion of the thyroarytenoid muscle was present in all 32, while other structures were invaded less frequently. In more than one half of these cases, the tumour had extended outside the laryngeal framework.

Twenty-five of the 110 laryngeal tumours arose in the supraglottic region. Tumours in this region tend to have "pushing" margins. One-quarter of these supraglottic tumours extended into the glottic region, a feature said to be uncommon. Nearly one-half of these tumours invaded the pre-epiglottic space (PES), the majority having arisen at the base of the epiglottis. Invasion of the pre-epiglottic space was an uncommon feature in tumours arising in other regions.

Only four of the 110 laryngeal tumours arose in the subglottic region. These tumours tend to be "ulcerofungating" and present themselves clinically only when far advanced. They tend to spread circumferentially and eventually

the muscles of the vocal cords. These tumours can also invade the hypopharyngeal mucosa through the crico-tracheal space There is then a risk of leaving tumour in this area at the time of surgery and a "recurrence above the stoma may occur

In general the method of whole organ serially sectioning has given the laryngologist much new information concerning growth and spread of laryngeal carcinoma. This information must be transferred into the clinical management of the patients with laryngeal carcinoma. The surgery must be modified according to the extension and type of tumour within the larynx.

Nodal metastasis occurred more frequently in supraglottic carcinomas than in glottic carcinomas It was also more common in larger tumours with destruction of cartilage and spread outside larynx, than for smaller tumours confined to the larynx. The importance of metastasis to the prelaryngeal (Delphian) node/s/ has been overemphasized. Involvement of these nodes occurred less frequently than expected Negative prelaryngeal nodes could be found close to a tumour that had spread outside the larynx

Hypopharyngeal carcinomas are less differentiated than laryngeal carcinomas. Extensive submucosal spread is a characteristic feature of these tumours. Piriform sinus carcinoma was the most common of these tumours and often involved laryngeal structures causing vocal cord fixation The large "multiregional carcinomas had a prominent superficial extension and a comparatively shallower deep extension. Two of the patients with hypopharyngeal carcinomas had received radiotherapy 30 and 54 years earlier for thyroid diseases. These tumours may be considered as irradiation induced carcinomas. There is a great risk involved in treating young/er/ people with radiotherapy Radiation induced tumours may appear usually two or more decades after irradiation Lymph node metastasis were more frequent in hypopharyngeal than in laryngeal carcinomas, which is one of the difficulties involved in the treatment of these tumours.

The study of the effect of preoperative irradiation revealed that different tumours had responded differently to the same type and amount of irradiation Some tumours were totally eradicated and replaced by fibrous connective tissue. In some cases scattered tumour nests were found in fibrous connective tissue and in others, only a minimal tumour response was present. We do not have any centripetal shrinkage of the tumour but islands of tumour can be left in the whole primary area involved. This particular point is of great importance especially when performing partial laryngectomies. The hypopharyngeal tumours were more often totally eradicated than the laryngeal tumours by the same type and dosage of preoperative irradiation. This difference in the response to irradiation must depend upon a difference in the biological behaviour of the tumours.

Irradiation effects were noted on many different tissues as the epithelium submucosal glands and blood vessels. No muscle or cartilage changes were observed The immediate preoperative irradiation did not give any histopathologically visible changes.

A long term follow up of our material will perhaps render further information as to which of the parameters studied have importance for the prognosis of the patients. There is also a great need for improved methods to enable better clinical assessment of the depth and penetration of the tumours. Until better methods of assessment have been developed there are many risks involved in the selecting of patients for partial (voice conservation) surgery especially after previous radiotherapy An increased interest in this field and concentration of the management of these tumours to oncologic centres with intimate collaboration between radiologists and surgeons will afford the patients the best treatment and consequently an increased chance of permanent cure

Zusammenfassung

Serienschnitte von ganzen Organen versorgen uns mit einer idealen Methode das Wachstum und die Ausbreitung der Tumoren zu studieren. Wir haben diese Methode benutzt um 139 Plattenepithelkarzinome in Larynx (110) und in Hypopharynx (29) zu untersuchen. Das Vorkommen von Larynxkarzinomen ist parallel zum Vorkommen von malignen Tumoren in Trachea und Bronchien — das Auftreten von beiden ist im Zuwachs begriffen. Maligne Tumoren des Larynx sind gewöhnlich Plattenepithelkarzinome mit mittelmässiger Differenzierung (Broders Grad II). Das Wachstum und die Ausbreitung von Larynxkarzinomen sind zum grossen Teil von der Lokalisation des ursprünglichen Tumors bestimmt. Wir haben versucht, die histopathologischen Grenzen der folgenden drei Larynxregionen (supraglottische, glottische und subglottische Region) zu definieren und abzugrenzen. Wir finden im Larynx viele anatomische Schranken, die die Tumorausbreitung zu begrenzen vermögen. Diese Schranken bilden mehrere anatomische Abteilungen — die wichtigsten sind das Spatium von Reinke, das prä-epiglottische Spatium (PES) und das paraglottische Spatium. 73 von den 110 Larynxkarzinomen stammten aus der glottischen Region. Wir betrachten den „Conus elasticus" als die histopathologische Grenze zwischen der glottischen und subglottischen Region und den inneren Winkel des Ventriculus laryngis als Grenze zwischen der glottischen und der supraglottischen Region. Vertikale Ausbreitung von glottischen Karzinomen (zur supraglottischen oder subglottischen Region) kommt sehr viel häufiger vor als horizontale Ausbreitung. Glottische Tumoren werden für eine lange Zeit vom knorpeligen Gerüst begrenzt. Wenn diese Karzinome sich aussen am Larynx ausbreiten, wachsen sie durch die schwachen Punkte des Kehlkopfgerüsts. Die Karzinome die den Commissura anterior umfassen, treten durch die Membrana cricothyreoidea aus, wenn sie sich subglottisch ausbreiten. Mehr als 75% der glottischen Tumoren die sich aussen am Larynx ausgebreitet haben kommen durch die Membrana cricothyreoidea. Diese Karzinome greifen oft den niedrigen Rand des Schildknorpels an und durchdringen ihn. Weiter rückwärts gelegene glottische Tumoren dehnen sich durch das Spatium cricothyreoideum aussen am Kehlkopfgerüst aus. Dieser Befund wurde besonders in den grösseren Karzinomen mit sub- und supraglottischer Ausbreitung beobachtet. Auch hier war der anliegende Schildknorpel und Ringknorpel angegriffen und durchbrochen worden.

Stimmbandfixierung war in unserer Serie ein gewöhnlicher klinischer Befund (39/110) und wir studierten die histopathologischen Ursachen dieser Fixierung. Der Musculus thyreoarytenoideus war in allen Fällen von Karzinomgeweben durchsetzt. Andere Strukturen sowie andere Muskeln die Art. cricoarytenoidea und das knorpelige Gerüst waren nicht so häufig angegriffen. Mehr als 50% von diesen Karzinomen hatten sich aussen am knorpeligen Gerüst angesetzt.

25 von 100 Larynxkarzinomen entstanden in der supraglottischen Region. Diese Tumoren weisen im allgemeinen einen schiebenden Rand auf. Ein Viertel dieser supraglottischen Karzinome war in die glottische Region und fast die Hälfte in das prä-epiglottische Spatium (PES) eingedrungen. Die Mehrzahl war an der Basis der Epiglottis entstanden. Das Eindringen von Karzinomgeweben in das präepiglottische Spatium war bei Karzinomen aus anderen Regionen ungewöhnlich.

Nur 4 von den 110 Larynxkarzinomen

involve the glottic region and/or the hypopharynx

Eight of the 110 laryngeal tumours were so large as to defy efforts to categorize them and these were referred to as "multiregional tumours. As would be expected, these tumours invaded many adjacent structures, frequently extended outside the larynx and often had metastasized to the cervical nodes at the time of surgery

In this series, less than 50% of patients with laryngeal carcinoma had a neck dissection at the time of laryngectomy The supraglottic tumours had the highest frequency of nodal metastasis The incidence was higher in those laryngeal tumours that had spread outside the larynx, than in those confined to the larynx. The prelaryngeal (Delphian) lymph node/s/ was involved infrequently by tumour (less than 10%) and when involved, was reached by direct tumour extension (through the cricothyroid membrane) rather than by lymphatic spread. There was no apparent correlation between metastasis in the prelaryngeal and those in the cervical nodes.

The incidence of hypopharyngeal carcinoma parallels the incidence of malignant tumours of the upper gastrointestinal tract (especially those of the oral cavity) rather than those of the upper respiratory tract Hypopharyngeal carcinomas tend to be rather poorly differentiated tumours (Broders grade III)

Two-thirds of the 29 hypopharyngeal carcinomas arose in the piriform sinus one quarter in the postcricoid region and the remainder were multiregional tumours. Extension of tumour beneath intact mucosa was a frequent finding in hypopharyngeal tumours The piriform sinus carcinomas often extended medially to invade laryngeal structures, causing laryngeal symptoms. Extension laterally with invasion of the thyroid ala was also frequently observed

Nearly 80% of the patients with hypopharyngeal carcinoma underwent a neck dissection at the time of laryngopharyngectomy Metastatic tumour was present in 65% of the neck dissection specimens.

In Toronto radiotherapy is a common mode of treatment for laryngeal and hypopharyngeal carcinoma. Only 19 of the 139 patients in this series had primary surgery

In a study of irradiation effect a large number of patients were treated by 5 500 rads Cobalt 60 followed by surgery 6 weeks later Fifty four of these patients are in this present series—34 with laryngeal carcinoma and 20 with hypopharyngeal carcinoma. Four distinct patterns of response to irradiation were seen no residual tumour (14) fibrosis with scattered tumour nests (19) minimal tumour response (19) and residual central tumour (2) Minimal tumour response was much more frequently seen in the laryngeal tumours (41%) than in the hypopharyngeal tumours (25%) In contrast, no residual tumour was present in 40% of the hypopharyngeal tumours, but in only 18% of the laryngeal tumours. It should be noted, however that most of the hypopharyngeal tumours did have positive cervical nodes at the time of operation.

Irradiation effect was also noted on other tissues Hyperkeratosis and acanthosis of the squamous epithelium and metaplasia of the very susceptible respiratory epithelium was a common finding Atrophy of the submucosal glands and typical vessel changes with intimal proliferation splitting of the elastica and fibrosis of the adventitia were other prominent signs of irradiation.

The present material represents only the initial portion of this study A five year follow up of all the patients in this series will allow us to determine which of the many histopathologic features, e g invasion of the thyroid cartilage invasion of the pre-epiglottic space (PES) spread through the cricothyroid membrane or space observed in this study of whole-organ sectioning will have prognostic significance

Nachuntersuchung aller Patienten nach 5 Jahren wird uns feststellen lassen, welche der vielen histopathologischen Befunde, die in dieser Untersuchung vorgelegt wurden (wie Angreifung und Durchdringung des knorpeligen Gerüsts, Ausbreitung durch die Membrana cricothyreoidea, Eindringung in das praepiglottische Spatium usw) eine prognostische Bedeutung haben.

entstammten der subglottischen Region. Diese Tumoren treten geschwürig und wuchernd auf und zeigen sich klinisch erst im fortgeschrittenen Stadium Sie pflegen die subglottische Region kreisförmig zu umwachsen bisweilen die glottische Region und/oder den Hypopharynx zu umfassen

8 von den 110 Larynxkarzinomen waren so gross, dass unsere Bemühungen sie zu klassifizieren fehlschlugen Diese Karzinome wurden von uns als multiregionale Tumoren bezeichnet. Wie erwartet: umfassten diese Tumoren viele angrenzende Strukturen und breiteten sich häufig aussen am Larynx aus und waren zur Zeit der Operation auch an den regionalen Lymphknoten metastasiert.

In dieser Serie hatten weniger als 50% der Patienten mit Larynxkarzinomen eine radikale Halslymphknotenausräumung zur Zeit der Operation. Die supraglottischen Karzinome hatten die höchste Frequenz von Lymphknotenmetastasen Die Frequenz von Lymphknotenmetastasen bei Tumoren die sich aussen am Larynx ausgebreitet hatten war höher als bei Tumoren die im Larynx begrenzt waren Der prä laryngeale Lymphknoten (Delphian Lymphknoten) war selten von Tumoren angegriffen (in weniger als 10%) und wenn es der Fall war meistens durch direkte Karzinomausdehnung und nicht durch lymphatische Ausbreitung Wir fanden keine sichtbare Beziehung zwischen Metastasen in den prä-laryngealen Lymphknoten und Metastasen in den Halslymphknoten

Die Häufigkeit des Vorkommens von Hypopharynxkarzinomen verläuft parallel mit der von malignen Tumoren in den Mund und oberen Magen Darm Bereichen, nicht aber der von Luftwegskarzinomen. Hypopharynx karzinome sind gewohnlich Plattenepithelkarzinome mit schlechter Differenzierung (Broders Grad III)

Zweidrittel von den 29 Hypopharynxkarzinomen waren im Sinus piriformis entstanden ein Viertel in der Postcricoid Region und die übrigen wurden von uns als multiregionale Tumoren bezeichnet. Ausbreitung von Hypopharynxkarzinomen unter einer unverletzten Schleimhaut wurde häufig festgestellt. Die Tumoren des Sinus piriformis breiteten sich oft medial aus, drangen in die laryngealen Strukturen ein und verursachten laryngeal Symptome Laterale Ausbreitung mit Eindringen in den Schildknorpel wurde auch häufig beobachtet

Fast 80% der Patienten mit Hypopharynxkarzinomen hatten eine radikale Halslymphknoten Ausräumung zur Zeit der Laryngohypopharyngektomie 65% von den Fallen mit radikaler Halslymphknoten Ausräumung hatten Metastasen in den Lymphknoten

In Toronto ist Strahlentherapie eine gewöhnliche Methode zur Behandlung von Larynx und Hypopharynxkarzinomen. Nur 19 von den 139 Patienten in dieser Serie hatten eine chirurgische Erstbehandlung erhalten.

In einer Untersuchung über die Wirkung der Strahlentherapie war eine grosse Zahl von Patienten mit 5 500 Rads Cobolt 60 bestrahlt worden die Operation erfolgte sechs Wochen später 54 der so behandelten Patienten wurden von uns untersucht — 34 mit Larynx karzinomen und 20 mit Hypopharynxkarzinomen Vier ausgeprägte Reaktionsmuster wurden beobachtet 14 ohne Residualkarzinome 19 mit zerstreuten Tumorresten im Bindegewebe 19 mit minimaler Tumorreaktion und 2 mit einem Tumorrest im Zentrum Minimale Tumorreaktion auf Bestrahlung war in Larynxtumoren viel häufiger (41%) als in Hypopharynxtumoren (25%) Im Gegensatz dazu hatten 40% der Hypopharynxkarzinome keine Residualkarzinome und nur 18% der Larynxkarzinome Es wurde festgestellt dass die meisten der Hypopharynxtumoren zur Zeit der Operationen an den Halslymphknoten metastasiert waren

Andere Gewebe zeigten auch postradiologische Veränderungen wie Metaplasie der Zylinderepithel, Atrophie von submukosen Drüsen und Verdickung der Intima und Fibrose der Adventitia der Gefässe.

Das vorliegende Material stellt nur den initialen Teil dieser Untersuchung dar Eine

Nachuntersuchung aller Patienten nach 5 Jahren wird uns feststellen lassen, welche der vielen histopathologischen Befunde die in dieser Untersuchung vorgelegt wurden (wie Angreifung und Druchdringung des knorpeligen Gerüsts, Ausbreitung durch die Membrana cricothyreoidea, Eindringung in das präepiglottische Spatium usw.) eine prognostische Bedeutung haben.

Acknowledgements

The authors wish to acknowledge the incal culable assistance of Professor D P Bryce whose stimulus and encouragement initiated and brought about the completion of this project.

The technical expertise provided by Mrs Janice Etty Mr Kenneth Ekem and Miss Patricia Tremmel and the patient collection of clinical data by Mrs Usha Bahrgava are greatfully acknowledged Dr T D R Briant and Dr William Anderson initiated the serial sectioning technique in this centre

The authors wish to thank Dr J O Godden for his advice during the preparation of this paper Harold Layne assisted in the photographic work and Pat Nielsen made the drawings. Mrs Jean Cetkovski and Mrs Monica Ungerholm typed this manuscript

This project was supported by the Charlie Conacher Cancer Research Fund, and the Ontario Cancer Treatment and Research Foundation (grant no 207)

PREFACE

The studies presented here were elaborated over a period of 11 years (1960–1971) during appointments in departments and institutes connected with The University of Aarhus, The University of Southern California, and The University of Odense.

The encouragement to commence working with the complicated subject – the aetiology of perceptive deafness came from Ole Bentzen, M.D., Ph.D. The State Hearing Rehabilitation Centre, Aarhus, who during my time in his department, and later on, inspired me and supported the efforts. For all this I am in great debt of gratitude. Audiometry Technician, Mrs. Annie Jentsch gave me able assistance in performing many of the audiometric evaluations, for which I extend my sincere thanks.

I am greatly indebted to my chief in the Department of Otolaryngology Professor H. C. Andersen, M.D. Ph.D., The University Hospital of Aarhus, and the chief of the Department of Neurosurgery Professor R. Malmros, M.D. Ph.D., The University Hospital of Aarhus, who both provided excellent working conditions for me and guided my efforts.

During the last four years of my stay in Aarhus, and later on during each phase of progress and realization of the many problems connected with my theme the chief of Neuropathology The University Hospital of Aarhus, Edith Reske-Nielsen, M.D., Ph.D. gave me invaluable support. Dr. Edith Reske-Nielsen is the co-author to three of the articles included in this monograph (the treatises A–C). Here she made the gross investigation of the brains plus the microscopy of brain sections. Too she assisted in the further elaboration of the comparative evaluation of the temporal bone and the brain findings. During the final compilation of the monograph she offered her assistance by counseling in some of the conclusions drawn from the collected findings of parts 1 and 2. Dr. Edith Reske-Nielsen has always given great consideration, sober criticism, and kind understanding to this project. The Department of Neuropathology she has endowed with a distinguished atmosphere of scientific enthusiasm, a never failing helpfulness and kindness, which it has been a special privelige to experience. For all this I am in great dept of thankfulness.

Mrs. Alice Strørup, Laboratory Technician in the Department of Neuropathology Århus Kommunehospital, offered valuable and skilfull support during all the phases of this project, which is kindly acknowledged.

Professor Emeritus Willy Munck, former chief, Department of Pathology Århus Kommunehospital, along with his assistants – especially Werner Petersen, Technical Assistant – offered their kind support by providing me with autopsy material.

Professor H. K. Kristensen, M.D. Ph.D. and his staff at the Temporal Bone Laboratory Rigshospitalet, Department of Otolaryngology Copenhagen, offered

The Professor of The Institute of Pathology A. Ringsted, M.D., Ph.D gave me invaluable support by freely providing me with material for which I am very thankfull.

Otto Jepsen, M.D Ph D., Professor of Otolaryngology The University Hospital of Odense, took a great interest in this research program. His kindness and soberness made it a daily pleasure for me to work in his department and discuss mutual scientific problems.

To Professor Horst Wullstein, M.D Ph.D University Clinic of Otolaryngology Würzburg Germany I am very obliged for the generous interest which he took in this investigation. Our many inspiring dialogues, the invaluable practical help provided during publication procedures, and his personal magnanimity constituted a highlight in scientific experience

Anita Engelbreth-Holm, M T.F translated this monograph. I hereby extend my sincere thanks for her assistance.

This project has been granted economical support from Statens Lægevidenskabelige Forskningsråd, Copenhagen and P Carl Petersen Fond, Copenhagen.

their service by staining the temporal bone sections included in part 1 of this monograph this I hereby acknowledge with special gratitude

During the busy years at different departments in Los Angeles, the possibility of establishing a Temporal Bone Vessel Laboratory was made available for me especially by the aid of William F House, M.D Research Director Otologic Medical Group Funds were provided in part by the Board of Trustees, Los Angeles Foundation of Otology for which I am extending my sincere thanks, especially to the President of the Foundation, Howard P House, M D Doctor William F House adviced me in many of the steps during the practical elaboration of the thick, cleared section technique, he too gave me invaluable support and encouragement, inspiration, – and was a generous friend. The laboratory was installed in the Raulston Research Building under the kind supervision of Aldon Miller M.D chairman of the Department of Otolaryngology the University of Southern California. For stimulation and practical help during this period I also express my appreciation to Clay R. Whitaker M.D., Associate Professor Department of Otolaryngology the University of Southern California.

The Temporal Bone Laboratory Otologic Medical Group Head Fred H Linthicum Jr., M.D., and George Kelemen, M.D offered me valuable assistance in the decalcification process, which is hereby gratefully acknowledged. This appreciation should be extended also to the laboratory technicians.

Jack Urban P.E. Urban Engineering Company helped in the construction of devises for the transillumination technique by which it was made possible to undertake preliminary investigations of the vascular anastomoses from the labyrinth to the middle ear It was a daily pleasure for me to work with him.

Antonio Mazzoni M D Department of Otolaryngology Ferrara Italy joined with me in the laboratory in Los Angeles one year after the onset of the project He later on moved to the Department of Anatomy the University of Odense Dr *Mazzoni should be thanked for the enthusiasm with which he cooperated on* many problems in the temporal bone anatomy He was most helpfull in working out technical details, in carrying material to Odense, and in participating in many professional discussions.

Cyril B Courville, M D Professor of Neurology Loma Linda University contributed with his tremendeous knowledge and understanding to the evaluation of pathological findings I deeply regret that he did not see the completion of this monograph before his death it was a sorrow for me that I did not experience the opportunity of cooperating with this noble and inspiring confrere in future projects

The investigation was completed at Odense University where Franz Bierring M.D Professor of Anatomy generously supported the project by means of space salary and equipment Professor Bierring s good advice and kindness very often gave me great inspiration during my work in his institute. I also wish to expres *my thanks to all other members of his staff* among whom I am especially indebted to Laboratory Technician Mrs. Ingelise Rohleder Laboratory Technician Miss Julie Levinsen and Medical Photographer E. Panton Furthermore I want to acknowledge *the helpfulness of* Bent Collatz Christensen M D

INTRODUCTION

According to the relevant literature the aetiology of perceptive hearing loss, especially the loss experienced late in life has been explained as a lesion involving peripheral as well as central sites in the auditory system. So far however systematic studies including a correlation of the clinical and pathological findings in the peripheral auditory organ have failed to demonstrate any parallelism between the degenerative changes involving the internal ear and the diagnosed loss of hearing (*Sporleder* 1899 *Crowe et al* 1934 *Saxén* 1952 *Schuknecht* 1955). Consequently these authors held that the aetiology of this type of hearing loss might include changes due to age in the cerebral auditory pathways and centres. *Matzker* (1958) and *Kirikae et al.* (1964) for instance have observed such changes in the brain stem. Unfortunately comparative studies of peripheral and central lesions in patients with well-defined perceptive deafness are not available

During my term, from 1959 to 1960 in Statens Hørecentral in Århus (The State Hearing Centre in Århus (Head. O Bentzen, M.D Ph D)) I was inspired to embark on such a comparative clinico-pathological study of structures in temporal bones and brains. In patients whose past medical histories included episodes of heart failure or sequelae of cerebral apoplexy the hearing loss seemed to be of a degree more severe than that otherwise observed in healthy individuals at equivalent ages In the course of the ensuing study the audiometric findings were evaluated and the degrees of the arteriosclerotic cerebral changes were determined the study included bilateral arteriography of carotid vessels as well (performed in the Neurosurgical Department G of Århus Kommunehospital (University Clinic in Århus) (Head. R. Malmros, M.D Ph D)) On the basis of these tests the severity of the cerebral lesions was found to be almost directly proportional to the hearing losses diagnosed by pure-tone audiometry According to these purely clinical, preliminary studies (*Hansen*, 1961) it seemed as if hearing losses which develop late in life might be attributable to cerebral lesions. The author found it worth consideration to compare structures in temporal bones and brains and hence exposed two groups of patients to audiometric examination, namely one group comprising 100 patients above the age of 65 years, and one group comprising 50 patients in the age group 20 to 60 years – unpublished data. Autopsy was performed in 14 cases, and the temporal bones and brains excised on these occasions were exposed to study The findings are discussed in Part 1 of the present monograph.

Gross inspection and microscopy of the brains were performed by Edith Reske Nielsen, M.D Ph.D Head of the Department of Neuropathology University Hospital, University of Århus.

These comparative studies of the degree of the pathological changes in the

INTRODUCTION

According to the relevant literature, the aetiology of perceptive hearing loss, especially the loss experienced late in life, has been explained as a lesion involving peripheral as well as central sites in the auditory system. So far, however, systematic studies including a correlation of the clinical and pathological findings in the peripheral auditory organ have failed to demonstrate any parallelism between the degenerative changes involving the internal ear and the diagnosed loss of hearing (*Sporleder* 1899, *Crowe et al.* 1934, *Saxén*, 1952, *Schuknecht* 1955). Consequently, these authors held that the aetiology of this type of hearing loss might include changes due to age in the cerebral auditory pathways and centres. *Matzker* (1958) and *Kirikae et al.* (1964), for instance, have observed such changes in the brain stem. Unfortunately, comparative studies of peripheral and central lesions in patients with well-defined perceptive deafness are not available.

During my term, from 1959 to 1960, in Statens Hørecentral in Århus (The State Hearing Centre in Århus (Head, O. Bentzen, M.D., Ph.D.)), I was inspired to embark on such a comparative clinico-pathological study of structures in temporal bones and brains. In patients whose past medical histories included episodes of heart failure or sequelae of cerebral apoplexy, the hearing loss seemed to be of a degree more severe than that otherwise observed in healthy individuals at equivalent ages. In the course of the ensuing study, the audiometric findings were evaluated and the degrees of the arteriosclerotic cerebral changes were determined; the study included bilateral arteriography of carotid vessels as well (performed in the Neurosurgical Department G of Århus Kommunehospital (University Clinic in Århus) (Head, R. Malmros, M.D., Ph.D.)). On the basis of these tests the severity of the cerebral lesions was found to be almost directly proportional to the hearing losses diagnosed by pure tone audiometry. According to these purely clinical preliminary studies (*Hansen*, 1961) it seemed as if hearing losses which develop late in life might be attributable to cerebral lesions. The author found it worth consideration to compare structures in temporal bones and brains and hence, exposed two groups of patients to audiometric examination, namely one group comprising 100 patients above the age of 65 years, and one group comprising 50 patients in the age group 70 to 60 years – unpublished data. Autopsy was performed in 14 cases, and the temporal bones and brains excised on these occasions were exposed to study. The findings are discussed in Part 1 of the present monograph.

Gross inspection and microscopy of the brains were performed by Edith Reske Nielsen, M.D., Ph.D., Head of the Department of Neuropathology, University Hospital, University of Århus.

These comparative studies of the degree of the pathological changes in the

PART 1

Clinical and Pathological Studies

The subject matter of Part 1 is the histological study of temporal bones and brains from patients who have been exposed to pure-tone audiometry with a view to amplifying our present insight into the pathological basis of perceptive hearing loss associated with old age.

Chapters I, II, III, IV and V are abstracts of treatises A, B and C.

various sections of the auditory system disclosed obvious discrepancies For instance the arterial system in the base of the skull might occasionally be a site of severe arteriosclerotic changes—even occlusion of the vascular lumen— while vessels as well as neural elements in the labyrinth apparently remained normal. This, however is hardly compatible with the general concept according to which arteries of the labyrinth are end arteries By means of injections of contrast matter the author tried consequently to clarify whether there might be a vascular connection between extracranical vessels via the osseous structures of the labyrinth to the vascular system in the labyrinth in excess of the supply to the peripheral hearing organ via intracranial vessels

The techniques used for such experimental injections into 43 temporal bones from man were elaborated by the author The series comprise temporal bones derived from senile patients as well as from much younger individuals

The findings obtained in these experiments are discussed in Part 2 of the present monograph

On the initiative of and in collaboration with William F House M D Otologic Medical Group Los Angeles the first part of the study was commenced It was supported by grants from the University of Southern California, Department of Otolaryngology (Head Aldon Miller M D) and the Otological Medical Foundation in Los Angeles (Head Howard P House M.D) Later the project has been completed in the Institute of Anatomy Odense University (Head F Bierring, M.D) One detail of practical interest (item 11 page 79) for the elaboration of the celloidine technique by which to study injected specimens was elaborated in cooperation with Antonio Mazzoni, M.D., Ferrara Italy who joined the laboratory one year after its establishment. Furthermore, he injected one colour 'microphil into ten of the temporal bones used for this study

The monograph comprises two parts a clinico-pathological and an anatomical experimental the object being to arrive at an explanation of some of the factors responsible for the development of perceptive deafness in particular that of the type pertaining to age"

PART 1

Clinical and Pathological Studies

The subject matter of Part 1 is the histological study of temporal bones and brains from patients who have been exposed to pure-tone audiometry with a view to amplifying our present insight into the pathological basis of perceptive hearing loss associated with old age

Chapters I II, III, IV and V are abstracts of treatises A, B and C.

various sections of the auditory system disclosed obvious discrepancies For instance, the arterial system in the base of the skull might occasionally be a site of *severe arteriosclerotic changes—even occlusion of the vascular lumen—* while vessels as well as neural elements in the labyrinth apparently remained normal. This, however is hardly compatible with the general concept according to which arteries of the labyrinth are end arteries. By means of injections of contrast matter the author tried consequently to clarify whether there might be a vascular connection between extracranical vessels via the osseous structures of the labyrinth to the vascular system in the labyrinth in excess of the supply to the peripheral hearing organ via intracranial vessels.

The techniques used for such experimental injections into 43 temporal bones from man were elaborated by the author The series comprise temporal bones derived from senile patients as well as from much younger individuals

The findings obtained in these experiments are discussed in Part 2 of the present monograph.

On the initiative of and in collaboration with, William F House, M.D., Otologic Medical Group Los Angeles, the first part of the study was commenced It was supported by grants from the University of Southern California, Department of Otolaryngology (Head Aldon Miller M.D) and the Otological Medical Foundation in Los Angeles (Head. Furthermore* he injected one colour "microphil" into ten of the temporal bones used for this study

The monograph comprises two parts. a clinico-pathological and an anatomical experimental the object being to arrive at an explanation *of some of the factors responsible for the development of perceptive deafness,* in particular that of the type "pertaining to age"

PART 1

Clinical and Pathological Studies

The subject matter of Part 1 is the histological study of temporal bones and brains from patients who have been exposed to pure-tone audiometry with a view to amplifying our present insight into the pathological basis of perceptive hearing loss associated with old age.

Chapters I II, III IV and V are abstracts of treatises A, B, and C.

CHAPTER I

Material and Methods

The series comprise a total of 14 patients who are classified into the following groups:

A 43-year-old patient with cerebral tumour and fluctuating hearing capacity treatise A. "Cortical hearing loss in a patient with glioblastoma

Twelve senile patients, all of whom except one were above the age of 65 years treatise B "Pathological studies in presbycusis. Cochlear and central findings in 12 aged patients"

One 65-year-old patient with Ménière s syndrome: treatise C. "Pathological studies in perceptive deafness. A patient with hydrops of the labyrinth

The techniques used for post-mortem inspection of brains and temporal bones and for the preparation of the histological specimens were identical in the three cited studies.

The patients were hospitalized in Arhus Kommunehospital (University Clinic in Arhus) or in departments attached, and died there during the period from 1961 to 1963 They had all been carefully examined, clinically as well as otologically pure-tone audiometry at frequencies of 250 500 1000 2000 4000, and 8000 cycles per second had been performed in all cases.

Organs and brains from all patients were inspected and the temporal bones were excised

The temporal bones were fixed in 4 / neutral formalin for at least one week and forwarded to the Temporal bone Laboratory of Professor H. K. Kristensen, Rigshospitalet (University Clinic, Copenhagen) Using the technique recommended by *Kristensen* (1949), the preparations were decalcified for about four or five months in a buffer solution composed of equal portions of 8 n formic acid and 1 n sodium formate, pH 2.2. The decalcified specimens were embedded in celloidin and cut in the horizontal plane in serial sections, the thickness of 15 micron.

Every 10th section was stained with Ehrlich s haematoxylin-eosin. Selected sections were exposed to the following specific stains: Nissl-substance stain using Anthracene blue pH 2, myelin sheath stain combined with connective tissue stain according to Kultschitzky + van Gieson axis cylinder stain, using Bodian s method and periodic acid-Schiff (PAS) according to McManus.

The brains were fixed for at least three weeks in 4 % neutral formalin.

A central block comprising cerebrum, brain stem, and cerebellum was removed in order to follow the acoustic pathways histologically Anteriorly the block was limited by the optic chiasm, laterally by the hippocampal gyri, and posteriorly by the cerebellum.

In the course of dissection of the block, the following regions were selected with special reference to a study of the acoustic pathways and nuclei.

1. The site of transition between the pons and the medulla oblongata, including the acoustic nerves
2. The pons at the site of the trigeminal nerves.
3. The mesencephalon, including the inferior colliculus.
4. The upper portion of the mesencephalon, including the medial geniculate body
5. Matter from both auditory centres the transverse gyri and the central portion of the superior temporal gyrus, together with
6. Supplementary tissue specimens from other parts of the brain beyond the auditory pathways and centres

The specimens were cut in sections, the thickness of 7 micron.

In excess of the routine stains such as haematoxylin-eosin, van Gieson, gallocyanin-chromalum (Einarson) and Mahon, the following specific stains were used axis cylinder stain according to Davenport modified McManus stain and toluidine blue

Note. If not otherwise stated the figures are designated in accordance with those in the treatises.

CHAPTER II

Neuropathological Analysis of the Temporal Bone and the Brain in a Patient with Glioblastoma and Fluctuating Hearing Capacity

According to a series of previously published studies (*Grahe* 1932 *Brunner* 1935 *Walker* 1951 *Nielsen & Berryman*, 1952 *Saltzman* 1952 *Drake & Mc Kenzie* 1953 *Greiner et al.*, 1953 1956 *Spiegel & Wycis* 1953 *Thiébaut et al.*, 1957 *Wycis et al.*, 1958 *Bentzen* 1961) audition of pure tones may vary parallel with pathological changes in the brain.

The present chapter which is a synopsis of treatise A, outlines briefly the most important data in the case history together with the clinical findings, in particular the audiometric findings, in a 43-year-old man whose hearing fluctuated parallel with pathological processes in the brain the lesions were partly attributable to the neurosurgical measures performed. The patient died of pulmonary embolism. The most important pathological findings are discussed and an attempt is made to have the clinical and pathological findings correlated.

The patient was admitted to the neurosurgical department G in November 1959 on account of progressing headaches associated with pressure exacerbation and explosive vomiting The clinical examination failed to reveal any anomalies. Papillary oedema of 1 dioptre and haemorrhages of a marbled pattern involving the background of the eye were manifest.

Audiometry of the 43-year-old patient showed that his hearing still was normal (fig 1)

The caloric reactions to irrigation with water at 30° C were normal. Ventriculography disclosed a space-filling process anteriorly in the right cerebral hemisphere and surgery exposed a tumour, measuring about 3 × 8 × 6 cm, in the posterior portion of the frontal region to the right, it was questionable whether surgery had been sufficiently radical at medial and profound sites towards the basal ganglia. The histological diagnosis was established as. glioblastoma (signed, Edith Reske-Nielsen)

Four days after surgery the patient managed to co-operate satisfactorily at the audiometry carried out in the ward The audiogram (fig. 1 corresponding to fig. 2 in treatise A) was comparable with that of a "presbycousis hearing curve obtained in cases of 75-year-old patients, according to the standard established by *Johansen* (1943) At this stage, a moderate, left-sided, central facial paresis occurred together with slight paresis of the left arm.

Six days after surgery audiometry was repeated. The patient's hearing had improved a little (fig. 1 corresponding to fig. 4 in treatise A)

In the course of dissection of the block, the following regions were selected with special reference to a study of the acoustic pathways and nuclei.

1 The site of transition between the pons and the medulla oblongata, including the acoustic nerves
2. The pons at the site of the trigeminal nerves.
3 The mesencephalon, including the inferior colliculus.
4 The upper portion of the mesencephalon including the medial geniculate body
5 Matter from both auditory centres the transverse gyri and the central portion of the superior temporal gyrus together with
6 Supplementary tissue specimens from other parts of the brain beyond the auditory pathways and centres

The specimens were cut in sections, the thickness of 7 micron.

In excess of the routine stains such as haematoxylin-eosin, van Gieson gallo-cyanin-chromalum (Einarson) and Mahon, the following specific stains were used axis cylinder stain according to Davenport modified McManus stain and toluidine blue.

Note. If not otherwise stated the figures are designated in accordance with those in the treatises.

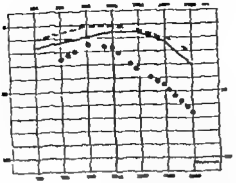

Fig 2 Hearing curves depicting the fluctuating audition, bilaterally symmetrical, in the patient discussed in chapter II. (1) Curve obtained by audiometry carried out in the patient' home (dashed line) (2) curve obtained prior to the second surgical intervention indicated by the tumour (fully drawn line) (3) curve obtained while cerebral oedema, provoked by the repeated surgery was in evidence (dotted line)

Ophthalmological examination on the same day revealed papillary oedema of 2 dioptres on both eyes.

The patient died suddenly two days after the last audiometric examination.

Immediately upon death, the brain was fixed *in situ* in a 4 / solution of neutral formalin.

Post-mortem inspection of the organs revealed a large pulmonary embolism, but otherwise normal findings.

The brain and the left temporal bone were removed.

Microscopy of the left temporal bone normal conditions (cf. treatise A)

Gross inspection of the brain. A defect, measuring 8 × 8 × 6 cm, was demonstrable in the right frontal lobe, extending upwards into the adjoining portion of the right temporal lobe which was lined by brain tissue infiltrated by the tumour The infiltration spread to the striate bodies, the internal capsule, and the anterior portion of the right thalamus. Through the corpus callosum the growth penetrated into the left frontal lobe at which site the infiltration extended medially and in front of the anterior horn.

Microscopy of the brain. The histological findings in the acoustic pathways, the nuclei, and in the cortical hearing centres have been discussed in detail in treatise A and consequently the pathological findings shall merely be outlined here, classified according to degrees of severity also the influence of the latter on the hearing is evaluated

I Chronic lesions which are presumed to suppress completely functions in the regions concerned.

1 Malacias localized to the right cortical hearing centre.
2 Disappearance and degeneration of the white substance in the right temporal lobe.
3 Atrophy and degeneration of the right inferior colliculus
4 Right-sided chronic degeneration of the white substance in the brain stem.

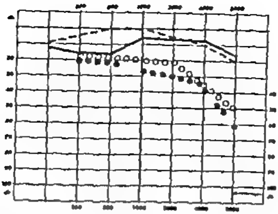

Fig 1 Hearing curves depicting the fluctuating audition, bilaterally symmetrical, in the patient discussed in chapter II.

Fully drawn line	= prior to	first surgical intervention			
Dotted line,	= four days after	–	–	–	
Circles,	= six days after	–	–	–	
Dashed line,	= five months after	–	–	–	

Five months later the patient was seen *in his own home in order to have an* audiometric follow-up He felt quite well and it was his intention to resume work His only complaint was som trouble with the fingers of his left hand which he was unable to control The audiogram showed normal conditions (dashed line in figs. 1 and 2, corresponding to fig. 6 in treatise A)

Eight months and two weeks after surgery the patient was re admitted to the department on account of a moderate loss of strength in the *left* extremities and an increased demand for sleep The patient did not realize his own condition in particular he did *not complain of hearing failure*

Clinical symptoms involving the right side of the brain were demonstrable Bilateral arteriography of the carotid arteries revealed recurrence of the tumour in the right cerebral hemisphere and ingrowth into the left cerebral hemisphere Ophthalmological examination showed papillary oedema of 2 dioptres while the otological findings were normal *According to the audiogram,* his *hearing had* deteriorated during the three month interval particularly *his* perception of tones in the high-frequency range (fig. 2, corresponding to fig 7 in treatise A)

Partial removal of the glioblastoma was performed, including resection of the entire frontal lobe on the right side and excision of large quantities of tumour tissue at the site of the foremost parietal lobe *but radical surgery was not practicable*

Transistorized audiometry was carried out in the ward 12 days after surgery on *which occasion the* patient managed to co-operate satisfactorily (fig 2, corresponding to fig 8 in treatise A) although he was still somewhat apathetic. The curve depicting the symmetrical hearing loss was found to equal that otherwise *obtained* in cases of 75-year-old patients, according to the standard established by *Johansen* (1943) In fact, the patient's hearing was just as good as it had been when he, eight months *earlier* had been suffering from cerebral oedema (figs 1 and 2)

loss. In the cases described by *Sérieux & Mignot* (1901) and by *Bramwell* (1927), post-mortem inspection of the brains exposed extensive destructive changes in the temporal lobes on either side. The patient described by *Mott* (1907) presented severe lesions localized to all transverse gyri, including the white substance on one side, while the pathological changes in the other hemisphere exclusively were localized to the cortex in the hearing centre. *Misch* (1928) observed that the lesion in his patient was localized only to the anteromedian part of the superior temporal gyrus of one hemisphere while the transverse gyri on the other side were totally destroyed. Finally, the extensive pathological, bilateral changes in the internal capsules involved also the acoustic radiation. In contrast, the cerebral cortex was found to remain normal in the deaf patient described by *Clark & Russell* (1938).

The above cited studies seem to indicate that the hearing capacity in man remains uninfluenced by unilateral hemispheric lesions whereas it will be extinct in patients in whom destructions involve the acoustic areas in both cerebral hemispheres. In the patient here discussed, the destruction of the right hearing centre may have been due to the severe oedema previously provoked by the tumour which involved the right cerebral hemisphere. Furthermore, ingrowth of the tumour into the right internal capsule may have been responsible for the severe right-sided, chronic degeneration of the brain stem, affecting in particular the efferent pathways. On the other hand, the degenerative changes in the trapezoid body and in the attached nuclei were rather mild, thereby suggesting that these were still functioning; this is commensurate with the clinical findings in the patient during intervals when cerebral oedema was absent and the patient's hearing on both ears was normal. The latter is in accord with findings obtained by *Mettler et al.* (1934) in experiments in which they destroyed one hearing centre together with the ipsilateral portion of the brain stem: the trapezoid body remained intact (fig. 3 corresponding to fig. 18 in treatise A).

Throughout the two postoperational periods in which the cerebral oedema was manifest, also *the left hemisphere* was partly out of action. In other words, both hearing centres were compromised: consequently the patient's hearing failed, in particular his hearing of sounds in the high-frequency range (fig. 4 corresponding to fig. 19 in treatise A).

The patient died of acute pulmonary embolism after the second surgical intervention, at a time when the cerebral oedema was manifest and the hearing loss clinically reminded of that observed by *Johansen* in a series of normal, 75 year-old patients (*Johansen* 1943). Considered from a patho-anatomical point of view the brain which was fixed *in situ* was in a condition like that observed at the audiometric examination when audition of pure tones had been lost because an acute, diffuse, cerebral oedema had been added to the chronic pathological lesions: consequently the left hearing centre had been blocked; the right hearing centre had been destroyed at an earlier stage (fig. 4 corresponding to fig. 19 in treatise A).

It is worth noticing that the acute changes of the brain stem were less marked than those of the cerebral hemisphere and that the left temporal bone remained intact.

II Acute lesions which are presumed to impair functions in the areas concerned

1 Oedema and degeneration involving the left cortical hearing centre
2 Severe, acute degeneration of the white substance in the left temporal lobe

III Lesions localized to other pathways and nuclei in the brain stem were small only and may not have exerted any clinically demonstrable influence on the patient's hearing It should be particulary stressed that the chronic and acute lesions were negligible in the right and left ventral and dorsal cochlear nuclei in the trapezoid body in the left inferior colliculus and in the medial geniculate body on either side

Discussion and Conclusion

Mettler et al (1934) demonstrated in experiments on dogs that extirpation of th cortical hearing centre in one hemisphere did not affect the hearing essentially whereas destruction involving both hemispheres would be responsible for a hearing loss of 70–75 decibel at a frequency of 1000 cycles per second (c p.s.) Further more this author observed that the acoustic value of crossed and non-crossed pathways in the brain stem was identical since one aspect of the brain stem together with the ipsilateral cerebral hemisphere might be injured without affecting the hearing capacity if only the trapezoid body was preserved

In previous studies by for instance *Nylén* (1939) *Lemoyne* (1944) *Bocca et al* (1955) *Carmichael et al* (1956) *Goldstein* (1961) and *Maspétiol et al* (1961) human audition was found to remain uninfluenced by lesions involving only one cerebral hemisphere The entire tone range may remain audible even after hemispherectomy (*Dandy* 1937)

Henschen (1920) did not observe loss of hearing in any of his 14 patients with lesions involving both hemispheres but an intact temporal lobe on one side

On the other hand, some reports have been concerned with bilateral lesions localized to the transverse gyri or the white substance in both cerebral hemispheres in which cases the hearing capacity apparently was extinct (*Strohmayer* 1901 *Campbell* 1905 *Henschen* 1916–1918 1920 *Fraser & Nelson* 1928)

As regards the patient discussed by *Fraser & Nelson* both cochleae had been inspected simultaneously The right cochlea was found to be normal while sequelae after a severe inflammation of the middle ear on the other side were in evidence

Special interest is attached to the reports on patients with normal hearing who had experienced previous episodes of cerebral apoplexy but lost their hearing later after repeated vascular episodes Five case histories of this type are available some of the patients were young, others were elderly individuals. The apoplectic episodes were attributable to embolism following endocarditis or mitral stenosis, to thrombosis in connection with cerebral arteriosclerosis or in one case to hae morrhages in cerebral hydatid cysts All of these patients survived for a couple of weeks after the vascular episode which had been responsible for their hearing

loss. In the cases described by *Sérieux & Mignot* (1901) and by *Bramwell* (1927), post-mortem inspection of the brains exposed extensive destructive changes in the temporal lobes on either side. The patient described by *Mott* (1907) presented severe lesions localized to all transverse gyri including the white substance on one side, while the pathological changes in the other hemisphere exclusively were localized to the cortex in the hearing centre. *Misch* (1928) observed that the lesion in his patient was localized only to the anteromedian part of the superior temporal gyrus of one hemisphere while the transverse gyri on the other side were totally destroyed. Finally the extensive pathological, bilateral changes in the internal capsules involved also the acoustic radiation. In contrast, the cerebral cortex was found to remain normal in the deaf patient described by *Clark & Russell* (1938).

The above cited studies seem to indicate that the hearing capacity in man remains uninfluenced by unilateral hemispheric lesions whereas it will be extinct in patients in whom destructions involve the acoustic areas in both cerebral hemispheres. In the patient here discussed, the destruction of the right hearing centre may have been due to the severe oedema previously provoked by the tumour which involved the right cerebral hemisphere. Furthermore, ingrowth of the tumour into the right internal capsule may have been responsible for the severe right-sided, chronic degeneration of the brain stem, affecting in particular the efferent pathways. On the other hand, the degenerative changes in the trapezoid body and in the attached nuclei were rather mild, thereby suggesting that these were still functioning: this is commensurate with the clinical findings in the patient during intervals when cerebral oedema was absent and the patient's hearing on both ears was normal. The latter is in accord with findings obtained by *Mettler et al.* (1934) in experiments in which they destroyed one hearing centre together with the ipsilateral portion of the brain stem: the trapezoid body remained intact (fig. 3 corresponding to fig. 18 in treatise A).

Throughout the two postoperational periods in which the cerebral oedema was manifest, *also the left hemisphere* was partly out of action. In other words, both hearing centres were compromised, consequently the patient's hearing failed, in particular his hearing of sounds in the high-frequency range (fig. 4 corresponding to fig. 19 in treatise A).

The patient died of acute pulmonary embolism after the second surgical intervention, at a time when the cerebral oedema was manifest and the hearing loss clinically reminded of that observed by *Johansen* in a series of normal, 75-year-old patients (*Johansen*, 1943). considered from a patho-anatomical point of view the brain which was fixed *in situ* was in a condition like that observed at the audiometric examination when audition of pure tones had been lost because an acute, diffuse, cerebral oedema had been added to the chronic pathological lesions: consequently the left hearing centre had been blocked, the right hearing centre had been destroyed at an earlier stage (fig. 4 corresponding to fig. 19 in treatise A).

It is worth noticing that the acute changes of the brain stem were less marked than those of the cerebral hemisphere and that the left temporal bone remained intact.

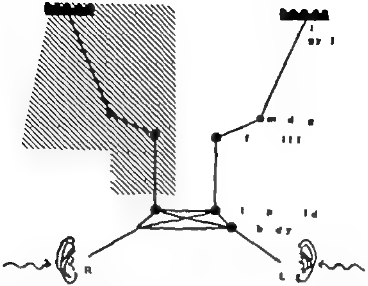

Fig. 3. The patient discussed in chapter II. Sketchy representation of localizations of the chronic pathological processes in relation to the cerebral auditory pathways and centres, hatched areas representing the pathological processes.

It seems reasonable to conclude on the basis of these clinical and pathological facts that the patient's loss of hearing, particularly his failing perception of tones in the high-frequency range, to a lesser degree of those in the low-frequency range (similar to features encountered in 75-year-old patients with presbycousis) may have been provoked by the recurring oedemas in the cerebral hemispheres. In other words, the hearing capacity is seen to fluctuate parallel with pathologically changing conditions in the brain.

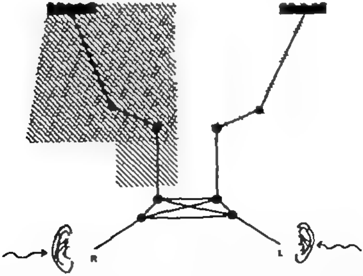

Fig. 4. The patient discussed in chapter II. Sketchy representation of localizations of the chronic (hatched area) and acute (dotted area) pathological processes in relation to the cerebral auditory pathways and centres.

CHAPTER III

Previous Studies of Senile Changes Involving the Peripheral Auditory Organ and the Central Auditory Pathways

The clinical findings in cases of perceptive hearing loss in old age are generally known, but the patho-anatomical factors responsible for the impaired hearing are much discussed, this applies to localization of lesions in and round about the peripheral auditory organ and the central auditory pathways as well as to the aetiology of these lesions.

Numerous studies are available in which audiometric findings have been collated with those obtained in patho-anatomical studies of the labyrinth.

Studies concerning the state of the central auditory pathways and centres in patients whose hearing is impaired due to age, however are less numerous.

The literature on these topics is comprehensive. The author has tried to select publications with relevance to the individual structures, fully realizing that there may be some overlapping.

A Changes involving the epithelial cochlear elements

Descriptions of the following lesions are on record. Flattening and degeneration of the organ of Corti, reduced number or complete absence, of hair cells and flattening of the supporting cells Occasionally the tectorial membrane may be thin and be incorporated into the formation of synechia Reissner's membrane has often been seen to adhere downwards over the organ of Corti (e.g. *Saxén* 1952 *Jørgensen* 1961)

According to the selected publications, the lesions may be attributable to (1) Angiosclerosis involving the internal ear (2) falling nutrition of the organ of Corti via the endolymph (3) atrophy due to old age (4) secondary atrophy owing to lesions of the spiral ganglion of the cochlea, and (5) changes to occur at terminal stages or after death

re (1) The incidence as well as the spread of angiosclerotic lesions increase parallel with age this is particularly true of lesions at the site of the vascular stria. According to *Fabinyi* (1931), *Crowe et al* (1934) *Schuknecht* (1955) and *Jørgensen* (1961), they occur uniformly throughout all coils. A parallelism between degrees of vascular changes and degeneration of the organ of Corti is not demonstrable (*Crowe et al.*, 1934 *Saxén* 1952 *Schuknecht* 1955 *Jørgensen* 1961). According to *Covell and Rogers* (1957), stria vessels of normal appearance may be encountered in areas displaying complete atrophy of the organ of Corti.

re (2) According to modern physiological and histochemical studies the organ of Corti is supplied through the endolymph secreted from the vascular stria, cf *Jørgensen* (1962) It is open to discussion, however whether a reduced secretion of the endolymph due to pathological processes in the vascular stria, may be responsible for the deafness to develop in old age since, as already mentioned, there is no correlation between the pathological processes in the vascular stria and those in the organ of Corti

re (3) Schuknecht (1955) declared that senile atrophy of the cochlea was the otological manifestation of processes due *to age which are in evidence in all* tissues throughout the body Such atrophy has been found to begin in the basal cochlear coil and to include all structures of the middle scale, for instance the *afferent and efferent fibres*

re (4) The epithelial changes may be secondary to the disappearance and degeneration of nerve cells in the spiral ganglion of the cochlea. This postulation is corroborated by the fact that epithelial changes rarely are encountered in cochlear areas where ganglion cells are intact (*Saxén* 1952 *Covell and Rogers* 1957) *Schuknecht* (1953) managed to destroy the neural elements in cats, escaping a development of secondary lesions of the organ of Corti.

re (5) Finally the histologically demonstrable changes in epithelial elements may have been provoked by such diseases as were responsible for the death of the patients or by changes to develop at terminal stages also the fixation time and fixation techniques may play some role (*Lange* 1937)

In addition to the lesions localized to the middle scale, *Mayer* (1919) observed a thickening of the basilar membrane at which site calcareous deposits were in evidence mainly in the basal coil Such lesions however have later been seen also in patients whose hearing was normal (*Crowe et al* 1934)

According to *Saxén* (1952) and *Fleischer* (1956), the above mentioned histopathological changes are not constant findings in the epithelial elements of the cochlea in elderly patients exclusively the same feature has actually been encountered even in 7 year-old patients by *Jørgensen* (1961)

Hence if these histopathological changes, which all were demonstrable by histological routine section and staining technique, were collated with those observed by audiometric examination of patients with presbycousis, it seemed highly improbable that the demonstrated pathological changes had been exclusively responsible for the loss of hearing. The reason may be that the clinical procedures the histological and the biochemical techniques were not sufficiently delicate to disclose such correlation. Accordingly a few studies in which these more advanced techniques were used shall be cited

Using the monaural balance test which according to *Pestalozza and Shore* (1955) represents a standard of the functioning capacity of hair cells these authors found values to be within the normal range in one half of all individuals in their series of patients with presbycousis.

Ruben (1963) found the cochlear microphonic potential (C M) to be within normal range in the basal coil in an elderly patient whose deafness to tones in the high frequency range was of the classic presbycousis type According to the

investigation, this indicates that functions of hair cells were fair at cochlear sites where high-frequency tones are perceived.

In a study of cochleae from elderly patients, *Bredberg* (1968) demonstrated by phase contrast microscopy of cochleae perfused with osmic acid that the disappearance of hair cells might be of different importance in the individual coils. At apical sites there tones in the frequency range 250 cycles per second are presumed to be perceived, the loss of hearing of tones in this range did not exceed 40 decibel even though up to 50 % or 75 % of the external hair cells had disappeared. Conversely in areas where tones in the range 8000 cycles per second are presumed to be perceived, a relatively smaller loss of external hair cells might result in a hearing impairment of a more severe degree. The author failed to demonstrate, however whether the *pro rata* loss of *internal* hair cells might be correlated with the loss of hearing of tones in the high frequency range.

Such lacking correlation between degrees of degenerative changes in the organ of Corti and the functioning capacity of the latter has been observed also in guinea pigs by *Schnieder and Janzer* (1969) These authors induced lesions of hair cells by means of the socalled "white noise As a standard of the degenerative changes, the lactose concentration in the perilymph was analysed and the results collated with the measured cochlear microphone potential were determined. Thus, the authors were able to demonstrate that even a considerable loss and degeneration of hair cells in the frequency range 4000 cycles per second did not reduce the cochlear microphone potential in the area of the basal cochlear coil.

On the basis of the above cited studies, it may be reasonable to presume that the degenerative changes in the epithelial elements of the cochlea hardly can be exclusively responsible for the hearing loss applying to tones in the high-frequency range, a loss which otherwise is typical in cases of presbycousis.

B Changes involving the vessels of the temporal bone and the vessels of the circle of Willis

Vascular changes in the membraneous portion of the cochlea are hardly contributory to a development of presbycousis. As previously mentioned, any parallelism between degrees of angiosclerosis in the vascular stria and degeneration of the organ of Corti is not in evidence and the same applies to vessels in the modiolus Besides, the pathological changes involving the cochlear vessels were not directly correlated with the degenerative lesions in the spiral ganglion of the cochlea (*Crowe et al.* 1934 *Saxén* 1952, *Schuknecht* 1955 *Covell and Rogers* 1957).

As regards the vascular changes involving the osseous capsule of the labyrinth, whether or not of any importance, *Gussen* (1968, 1969) ascertained, on the basis of conventionally stained celloidin sections, that the vascular supply apparently remained satisfactory even in very old subjects in fact, it did not deviate much from that observed in young subjects. In patients with presenile arteriosclerosis, however a development of thrombi in these vessels seemed to be more common (*Gussen* 1969).

investigation, this indicates that functions of hair cells were fair at cochlear sites where high-frequency tones are perceived.

In a study of cochleae from elderly patients, *Bredberg* (1968) demonstrated by phase contrast microscopy of cochleae perfused with osmic acid that the disappearance of hair cells might be of different importance in the individual coils. At apical sites where tones in the frequency range 250 cycles per second are presumed to be perceived, the loss of hearing of tones in this range did not exceed 40 decibel, even though up to 50 / or 75 / of the external hair cells had disappeared. Conversely in areas where tones in the range 8000 cycles per second are presumed to be perceived, a relatively smaller loss of external hair cells might result in a hearing impairment of a more severe degree. The author failed to demonstrate, however whether the *pro rata* loss of *internal* hair cells might be correlated with the loss of hearing of tones in the high frequency range.

Such lacking correlation between degrees of degenerative changes in the organ of Corti and the functioning capacity of the latter has been observed also in guinea pigs by *Schneider and Janzer* (1969) These authors induced lesions of hair cells by means of the socalled white noise As a standard of the degenerative changes, the lactose concentration in the perilymph was analysed and the results collated with the measured cochlear microphone potential were determined. Thus, the authors were able to demonstrate that even a considerable loss and degeneration of hair cells in the frequency range 4000 cycles per second did not reduce the cochlear microphone potential in the area of the basal cochlear coil.

On the basis of the above cited studies, it may be reasonable to presume that the degenerative changes in the epithelial elements of the cochlea hardly can be exclusively responsible for the hearing loss applying to tones in the high-frequency range, a loss which otherwise is typical in cases of presbyacusis.

B Changes involving the vessels of the temporal bone and the vessels of the circle of Willis

Vascular changes in the membraneous portion of the cochlea are hardly contributory to a development of presbyacusis. As previously mentioned, any parallelism between degrees of angiosclerosis in the vascular stria and degeneration of the organ of Corti is not in evidence and the same applies to vessels in the modiolus Besides, the pathological changes involving the cochlear vessels were not directly correlated with the degenerative lesions in the spiral ganglion of the cochlea (*Crowe et al* 1934 *Saxén* 1952 *Schuknecht* 1955 *Covell and Rogers* 1957)

As regards the vascular changes involving the osseous capsule of the labyrinth, whether or not of any importance *Gussen* (1968, 1969) ascertained, on the basis of conventionally stained celloidin sections, that the vascular supply apparently remained satisfactory even in very old subjects, in fact, it did not deviate much from that observed in young subjects. In patients with presenile arteriosclerosis, however a development of thrombi in these vessels seemed to be more common (*Gussen*, 1969)

It is still open to discussion whether vascular changes involving the peripheral auditory organ may be correlated with changes in the cerebral vessels and, likewise, whether changes in the circle of Willis may be correlated with those in vessels running through the internal auditory canal

Saxén (1952) observed angiosclerosis in vessels of the internal ear although coincident lesions of vessels in the internal auditory canal and those at the base of the brain were absent in renal vessels, however arteriolosclerosis was in evidence. On the other hand *Jørgensen* (1961) declared that there might be a certain correlation between vascular changes in the vascular stria and those in the cerebral vessels, in particular in those at the base of the brain On the basis of findings in a series of old patients, *Ishii* (1967) concluded that pathological changes in the basilar arteries, including the anterior inferior cerebellar arteries and those in the internal auditory canals, need not be correlated with lesions affecting the various structures of the internal ear

In a study of a series of senile patients, *Fabinyi* (1931) compared the audiometric findings with the pathological processes in the large cerebral arteries. There was apparently some correlation between loss of hearing of tones in the high-frequency range and degrees of cerebral arteriosclerosis, but the relation between the loss of hearing of tones in the high frequency range and changes in internal auditory canal vessels was less clear-cut.

C Histopathological changes involving the spiral ganglion of the cochlea

Disappearance and degeneration of ganglion cells in the spiral ganglion of the cochlea are mainly demonstrable in the basal coil and represent the patho-anatomical process most constantly encountered in the labyrinth of elderly patients (*Crowe et al* 1934 *Saxén* 1952 *Schuknecht* 1955 and *Jørgensen* 1961) According to *Fleischer* (1956) these lesions were the only ones to intensify parallel with advancing years consequently he suggested that the neural changes might be solely responsible for the development of presbycousis

Fabinyi (1931) and *Crowe et al* (1934) have declared that degrees of changes in the ganglion cells of the basal coil might be correlated, though not absolutely with the degrees of hearing loss applying to tones in the high frequency range In patients whose hearing was severely impaired, *Crowe et al* (1934) and *Saxén* (1952) observed, however that pathological processes involving the spiral ganglion might occasionally be of moderate degree

In patients whose hearing is normal and who perceive tones in the high- as well as the low-frequency range, the percentage of damaged ganglion cells in the basal coil has been differently calculated by the individual authors for instance, it has been found to range at 50 (*Crowe et al* 1934) at 75 (*Schuknecht* 1955), even up to 80 (*Citron et al.* 1963)

In a series of patients with presbycousis, *Saxén* (1952) observed that the percentage of degenerated nerve cells in the basal coil often might range below 50 while the percentage of ganglion cells in the middle and apical coil generally was

within normal range, even though perception of tones in the low-frequency range was found to vary greatly from patient to patient.

Obviously a loss of hearing need not be correlated with a degeneration of neural elements, whether in basal, middle, or apical coils. Hence it seems highly improbable if patho-anatomical lesions in the spiral ganglion were solely responsible for a development of presbycousis.

"The reason why the atrophic change selects the basal end is as great a mystery to me as the process of ageing itself" (*Schuknecht* 1955)

Evidently such changes in the spiral ganglion need not be secondary to a degeneration of the efferent pathways in the cochlea and, in fact, atrophic ganglion cells were not in evidence several weeks after bisection of the olivo-cochlear bundle (*Rasmussen*, 1953).

D. *Degeneration of the acoustic nerve throughout the tractus spiralis foraminosus and the internal auditory canal*

Sërcer and Krmpotić (1958) observed some hyperosteotic lesions at the site of tractus spiralis foraminosus, mainly involving the area where nerve fibres emerge from the basal coil. These findings may explain to some extent why perception of high tones may be impaired in old age, although other authors have failed to confirm the phenomenon.

According to *Crowe et al.* (1934) the patho-anatomical lesions involving the cochlear nerve throughout the internal auditory canal may be of a degree more pronounced than that of the degenerative changes in the organ of Corti.

It remains obscure, however, whether such changes may be responsible for the loss of hearing in old age. *Neff* (1947) found that tones in the high-frequency range were imperceptible to experimental animals if more than 50 % of all fibres in the cochlear nerve had been bisected, in contrast, *Schuknecht and Woellner* (1953) who destroyed 75 % of this nerve in cats, avoided injuring the hearing.

In patients with acoustic neurinomas, severe degeneration of the cochlear nerve need not be associated with impaired perception of pure tones (*Schuknecht and Woellner* 1955 *Jerger* 1960 *Citron et al.*, 1963 *House* 1968)

It does not appear from the above cited studies, however whether the histo-pathologically demonstrable lesions were localized to the peripheral (Schwann's) or the central (glial) part of the cochlear nerve.

Thus, it can be established that many investigators have pointed to the fact that the pathological changes of structures in the temporal bone are not exclusively responsible for a loss of hearing late in life.

E. *Pathological processes involving the cerebral auditory pathways and centres*

Reports concerning the status of the auditory areas in the brains of patients with presbycousis are scarce.

According to *Scheidegger* (1963), several types of diffuse, degenerative lesions

It is still open to discussion whether vascular changes involving the peripheral auditory organ may be correlated with changes in the cerebral vessels and likewise, whether changes in the circle of Willis may be correlated with those in vessels running through the internal auditory canal

Saxén (1952) observed angiosclerosis in vessels of the internal ear although coincident lesions of vessels in the internal auditory canal and those at the base of the brain were absent In renal vessels, however arteriolosclerosis was in evidence. On the other hand, *Jørgensen* (1961) declared that there might be a certain correlation between vascular changes in the vascular stria and those in the cerebral vessels, in particular in those at the base of the brain. On the basis of findings in a series of old patients, *Ishii* (1967) concluded that pathological changes in the basilar arteries, including the anterior inferior cerebellar arteries and those in the internal auditory canals, need not be correlated with lesions affecting the various structures of the internal ear

In a study of a series of senile patients *Fabinyi* (1931) compared the audiometric findings with the pathological processes in the large cerebral arteries. There was apparently some correlation between loss of hearing of tones in the high-frequency range and degrees of cerebral arteriosclerosis, but the relation between the loss of hearing of tones in the high frequency range and changes in internal auditory canal vessels was less clear-cut

C Histopathological changes involving the spiral ganglion of the cochlea

Disappearance and degeneration of ganglion cells in the spiral ganglion of the cochlea are mainly demonstrable in the basal coil and represent the patho-anatomical process most constantly encountered in the labyrinth of elderly patients (*Crowe et al* 1934 *Saxén* 1952 *Schuknecht* 1955 and *Jørgensen* 1961) *According to Fleischer* (1956) these lesions were the only ones to intensify parallel with advancing years consequently he suggested that the neural changes might be solely responsible for the development of presbycousis

Fabinyi (1931) and *Crowe et al.* (1934) have declared that degrees of changes in the ganglion cells of the basal coil might be correlated, though not absolutely with the degrees of hearing loss applying to tones in the high frequency range In patients whose hearing was severely impaired *Crowe et al* (1934) and *Saxén* (1952) observed, however that pathological processes involving the spiral ganglion might occasionally be of moderate degree

In patients whose hearing is normal and who perceive tones in the high as well as the low-frequency range, the percentage of damaged ganglion cells in the basal coil has been differently calculated by the individual authors for instance, it has been found to range at 50 (*Crowe et al* 1934) at 75 (*Schuknecht* 1955) even up to 80 (*Citron et al.* 1963)

In a series of patients with presbycousis *Saxén* (1952) observed that the percentage of degenerated nerve cells in the basal coil often might range below 50 while the percentage of ganglion cells in the middle and apical coil generally was

CHAPTER IV

Analysis of the Pathological Processes Involving the Peripheral Auditory Organ and Central Pathways in Twelve Senile Patients Whose Loss of Perceptive Hearing was Verified

As mentioned in chapter III, numerous authors have discussed the patho-anatomical processes involving the cochlea as well as the central auditory pathways, processes which may have been responsible for the loss of hearing in old age the authors concerned have correlated the loss of hearing with pathological processes localized exclusively to cochlear structures or to sites within the central auditory pathways and centres.

In a further attempt to define the patho-anatomical factors responsible for the loss of hearing in old age and to localize the origin, or origins, of such loss, a parallel has been drawn between the findings obtained by audiometry and the pathological lesions of the central auditory pathways and lesions of the temporal bone structures As far as the author is aware, this type of study has not yet been performed

According to patho-anatomical criteria, the 12 patients comprised in the series can be classified into four groups of 8 2, 1 an 1 patients. The patients concerned have previously been discussed in treatise B of which an abstract follows

Group I 8 patients

The past medical histories of these eight patients were identical which applies also to the audiological and patho-anatomical findings, though individual variations might be encountered.

Table 1 represents a survey of findings by audiometry incidence of intercurrent diseases, causes of death, and autopsy findings in organs from the eight patients, the series comprised four men and four women at ages above 80 years except one who was only 66 years old

The blood pressure was normal according to age in all patients except in the patient classified into group III.

The past audiological histories contained no data which might explain why these patients had lost hearing indeed patients nos. 3 and 5 had experienced left sided otitis media while the remaining six patients had perceptive deafness, presenting symmetrical hearing curves (fig 5 corresponding to figs. 15–22 in treatise B)

The average value of intelligibility thresholds in the ranges 250 500, and 1000 cycles per second, i.e. the low-frequency ranges, varied from 10 decibel to 60 decibel As regards the high-frequency range, audition was severely impaired in all

might occur in brains of presenile or senile patients, for instance, cerebral arterio-sclerosis, senile atrophy Alzheimer's syndrome, Pick's disease, and the socalled presenile spongious cerebral atrophy There is reason to suppose that similar lesions may be encountered also in the cerebral auditory pathways and centres
